(Dated: April 23, 2015)

Atomistic molecular simulations are a powerful way to make quantitative predictions, but the accuracy of these predictions depends entirely on the quality of the forcefield employed. While experimental measurements of fundamental physical properties offer a straightforward approach for evaluating forcefield quality, the bulk of this information has been tied up in formats that are not machine-readable. These formats require substantial human effort to compile benchmark datasets which are prone to accumulation of human errors, hindering the development of reproducible benchmarks of forcefield accuracy. Here, we examine the feasibility of benchmarking atomistic forcefields against the NIST ThermoML data archive of physicochemical measurements, which aggregates thousands of experimental measurements in a portable, machine-readable, self-annotating format. As a proof of concept, we present a detailed benchmark of the generalized Amber small molecule forcefield (GAFF) using the AM1-BCC charge model against measurements (specifically bulk liquid densities and static dielectric constants at ambient pressure) automatically extracted from the archive, and discuss the extent of available data. The results of this benchmark highlights a general problem with fixed-charge forcefields in the representation of liquids of low dielectric.

Keywords: molecular mechanics forcefields; forcefield parameterization; forcefield accuracy; forcefield validation; mass density; static dielectric constant; biomolecular simulation

I. INTRODUCTION

Recent advances in hardware and software for molecular dynamics simulation now permit routine access to atomistic simulations at the 100 ns timescale and beyond [1]. Leveraging these advances in combination with consumer GPU clusters, distributed computing, or custom hardware has brought microsecond and millisecond simulation timescales within reach of many laboratories. These dramatic advances in sampling, however, have revealed deficiencies in forcefields as a critical barrier to enabling truly predictive simulations of physical properties of biomolecular systems.

Protein and water forcefields have been the subject of numerous benchmarks [2] and enhancements [3–5], with key outcomes including the ability to fold fast-folding proteins [6–8], improved fidelity of water thermodynamic properties [9], and improved prediction of NMR observables. Although small molecule forcefields have also been the subject of benchmarks [10] and improvements [11], such work has typically focused on small perturbations to specific functional groups. For example, a recent study found

that modified hydroxyl nonbonded parameters led to improved prediction of static dielectric constants and hydration free energies [11]. There are also outstanding questions of generalizability of these targeted perturbations; it is uncertain whether changes to the parameters for a specific chemical moiety will be compatible with seemingly unrelated improvements to other groups. Addressing these questions requires establishing a community agreement on shared benchmarks that can be easily replicated among laboratories to test proposed forcefield enhancements and expanded as the body of experimental data grows.

A key barrier to establishing reproducible and extensible forcefield accuracy benchmarks is that many experimental datasets are heterogeneous, paywalled, and unavailable in machine-readable formats (although notable counterexamples exist, e.g. the RCSB [12], FreeSolv [13], and the BMRB [14]). While this inconvenience is relatively minor for benchmarking forcefield accuracy for a single target system (e.g. water), it becomes prohibitive for studies spanning the relevant chemical space. To ameliorate problems of data archival, the NIST Thermodynamics Research Center (TRC) has developed a IUPAC standard XML-based format—ThermoML [15]—for storing physicochemical measurements, uncertainties, and metadata. Experimental researchers publishing measurements in several journals (J. Chem. Eng. Data, J. Chem. Therm., Fluid Phase Equil., Therm. Acta, and Int. J. Therm.) are guided through a data archival process that involves sanity checks, conversion to a standard machine-readable format, and archival at the TRC

(<http://trc.nist.gov/ThermoML.html>).

Here, we examine the ThermoML archive as a potential source for providing the foundation for a reproducible, extensible accuracy benchmark of biomolecular forcefields. In particular, we concentrate on two important physical property measurements easily computable in many simulation codes—neat liquid density and static dielectric constant measurements—with the goal of developing a standard benchmark for validating these properties in fixed-charge forcefields of drug-like molecules and biopolymer residue analogues. These two properties provide sensitive tests of forcefield accuracy that are nonetheless straightforward to calculate. Using these data, we evaluate the generalized Amber small molecule forcefield (GAFF) [16, 17] with the AM1-BCC charge model [18, 19] and identify systematic biases to aid further forcefield refinement.

METHODS

A. ThermoML Archive retrieval and processing

A tarball archive snapshot of the ThermoML Archive was obtained from the the NIST TRC on 13 Sep 2014. To explore the content of this archive, we created a Python (version 2.7.9) tool (ThermoPyL: <https://github.com/choderalab/ThermoPyL>) that formats the XML content into a spreadsheet-like format accessible via the Pandas (version 0.15.2) library. First, we obtained the XML schema (<http://media.iupac.org/namespaces/ThermoML/ThermoML.xsd>) defining the layout of the data. This schema was converted into a Python object via PyXB 1.2.4 (<http://pyxb.sourceforge.net/>). Finally, this schema was used to extract the data into Pandas [20] dataframes, and the successive filters data filters described in Section III A were applied.

B. Simulation

1. Preparation

Simulation boxes containing 1000 molecules were constructed using PackMol version 14-225 [21, 22] wrapped in an automated tool. Packmol boxes volumes were chosen to accommodate twice the van der Waals volume of the enclosed atoms. AM1-BCC [18, 19, 23] charges were generated with the OpenEye Python Toolkit version 2015-2-3 [24], using the `oequacpac.OEAssignPartialCharges` module with the `OECharges_AM1BCCSym` option, which utilizes a conformational expansion procedure (using `oeomega.OEOmega`) prior to charge fitting to minimize artifacts from intramolecular contacts. The `OEOmega` selected conformer was then processed using `antechamber` (with `parmchk2`) and `tleap` in AmberTools 14 [25] to produce `prmtop` and `inpcrd` files, which were then read into OpenMM using the `simtk.openmm.app` module. Simulation code used

libraries `gaff2xml` 0.6.4 [26], OpenMM 6.3 [27], and MD-Traj 1.3 [28]. Exact commands to install various dependencies can be found in section A 1.

2. Equilibration and production

Boxes were first minimized and equilibrated for 10^7 steps with an equilibration timestep of 0.4 fs and a collision rate of 5 ps^{-1} . Production simulations were performed with OpenMM 6.2 [27] using a Langevin integrator (with collision rate 1 ps^{-1}) and a 1 fs timestep, as we found that timesteps of 2 fs timestep or greater led to a significant timestep dependence in computed equilibrium densities (Table 4).

Pressure control to 1 atm was achieved with a Monte Carlo barostat utilizing molecular scaling and automated step size adjustment during equilibration, with volume moves attempted every 25 steps. The particle mesh Ewald (PME) method [29] was used with a long-range cutoff of 0.95 nm and a long-range isotropic dispersion correction. PME grid and spline parameters were automatically selected using the default settings in OpenMM 6.3 for the CUDA platform.

Simulations were continued until automatic analysis showed standard errors in densities were less than $2 \times 10^{-4} \text{ g/mL}$. Automatic analysis was run every 1 ns of simulation time, and utilized the `detectEquilibration` method in the `timeseries` module of `pymbar` 2.1 [30] to automatically trim the initial portion of the simulation with strong far-from-equilibrium behavior by maximizing the number of effectively uncorrelated samples in the remainder of the production simulation as determined by autocorrelation analysis. Statistical errors were computed after subsampling the data to produce effectively uncorrelated equilibrium samples by $\delta^2 \rho \approx \text{var}(\rho)/N_{\text{eff}}$, where $\text{var}(\rho)$ is the sample variance of the density and N_{eff} is the number of effectively uncorrelated samples. With this protocol, we found starting trajectory lengths of 14000 ± 11000 frames (250 fs each), discarded regions of 1800 ± 5600 , and statistical inefficiencies of 30 ± 34 (mean \pm standard deviation).

Instantaneous densities were stored every 250 fs, while trajectory snapshots were stored every 5 ps.

3. Data analysis and statistical error estimation

Trajectory analysis was performed using OpenMM 6.3 [27] and MD-Traj 1.3 [28]. Mass density ρ was computed via the relation,

$$\rho = \left\langle \frac{M}{V} \right\rangle, \quad (1)$$

where M is the total mass of all particles in the system and V is the instantaneous volume of the simulation box.

Static dielectric constants were calculated using the dipole fluctuation approach appropriate for PME with conducting (“tin-foil”) boundary conditions [9, 31], with the total system box dipole μ computed from trajectory snapshots

159 using MDTraj 1.3 [28].

$$\epsilon = 1 + \frac{4\pi}{3} \frac{\langle \mu \cdot \mu \rangle - \langle \mu \rangle \cdot \langle \mu \rangle}{\langle V \rangle k_B T} \quad (2)$$

160 Statistical uncertainties were computed by bootstrap-
 161 ping uncorrelated samples following discarding the
 162 automatically-determined initial portion of the simulation
 163 to equilibration, as described in Section II B 2. All reported
 164 uncertainties represent an estimate of one standard
 165 deviation of the mean unless otherwise reported.

166 4. Code availability

167 Data analysis, intermediate data (everything but trajec-
 168 tories), and figure creation code for this work is available at
 169 <https://github.com/choderalab/LiquidBenchmark>.

170 III. RESULTS

171 A. Extracting neat liquid measurements from the NIST TRC 172 ThermoML Archive

173 As described in Section II A, we retrieved a copy of the
 174 ThermoML Archive and performed a number of sequen-
 175 tial filtering steps to produce an ThermoML extract rele-
 176 vant for benchmarking forcefields describing small organic
 177 molecules. As our aim is to explore neat liquid data with
 178 functional groups relevant to biopolymers and drug-like
 179 molecules, we applied the following ordered filters, start-
 180 ing with all data containing density or static dielectric con-
 181 stants:

- 182 1. The measured solution contains only a single compo-
 183 nent (e.g. no binary mixtures)
- 184 2. The molecule contains only druglike elements (de-
 185 fined here as H, N, C, O, S, P, F, Cl, Br)
- 186 3. The molecule has ≤ 10 heavy atoms
- 187 4. The measurement was performed in a biophysically
 188 relevant temperature range ($270 \leq T \text{ [K]} \leq 330$)
- 189 5. The measurement was performed at ambient pres-
 190 sure ($100 \leq P \text{ [kPa]} \leq 102$)
- 191 6. Only measurements in liquid phase were retained
- 192 7. The temperature and pressure were rounded to
 193 nearby values (as described below), averaging all
 194 measurements within each group of like conditions
- 195 8. Only conditions (molecule, temperature, pressure)
 196 for which *both* density and dielectric constants were
 197 available were retained

Filter step	Number of measurements remaining	
	Mass density	Static dielectric
1. Single Component	136212	1651
2. Druglike Elements	125953	1651
3. Heavy Atoms	71595	1569
4. Temperature	38821	964
5. Pressure	14103	461
6. Liquid state	14033	461
7. Aggregate T, P	3592	432
8. Density+Dielectric	246	246

TABLE I: **Successive filtration of the ThermoML Archive.**

A set of successive filters were applied to all measurements in the ThermoML Archive (accessed 13 Sep 2014) that contained either mass density or static dielectric constant measurements. Each column reports the number of measurements remaining after successive application of the corresponding filtration step.

198 The temperature and pressure rounding step was moti-
 199 vated by common data reporting variations; for example,
 200 an experiment performed at the freezing temperature of
 201 water and ambient pressure might be entered as either
 202 101.325 kPa or 100 kPa, with a temperature of either 273 K
 203 or 273.15 K. Therefore all pressures within the range [kPa]
 204 ($100 \leq P \leq 102$) were rounded to exactly 1 atm (101.325
 205 kPa). Temperatures were rounded to one decimal place in
 206 K.

207 The application of these filters (Table I) leaves 245
 208 conditions—where a *condition* here indicates a (molecule,
 209 temperature, pressure) tuple—for which both density and
 210 dielectric data are available. The functional groups present
 211 in the resulting dataset are summarized in Table II; see Sec-
 212 tion II A for further description of the software pipeline used.

213 B. Benchmarking GAFF/AM1-BCC against the ThermoML 214 Archive

215 1. Mass density

216 Mass densities of bulk liquids have been widely used
 217 for parameterizing and testing forcefields, particularly the
 218 Lennard-Jones parameters representing dispersive and repul-
 219 sive interactions [33, 34]. We therefore used the present
 220 ThermoML extract as a benchmark of the GAFF/AM1-BCC
 221 forcefield (Fig. 1).

222 Overall, the densities show reasonable accuracy, with a
 223 root-mean square (RMS) relative error over all measure-
 224 ments of $2.9 \pm 0.1\%$, especially encouraging given that this
 225 forcefield was not designed with the intention of model-
 226 ing bulk liquid properties of organic molecules [16, 17] This
 227 is reasonably consistent with previous studies reporting
 228 agreement of 4% on a different benchmark set [10].

229 For a given compound, the errors are roughly similar at
 230 different temperatures (Fig. 7). Overall, the predictions give
 231 an average density of $.948 \pm 0.009 \text{ g/mL}$, while the mea-
 232 surements give an average density of $.928 \pm 0.008 \text{ g/mL}$.

Functional Group	Occurrences
1,2-aminoalcohol	4

sulfoxide	1
tertiary aliphatic amine (trialkylamine)	3
tertiary amine	3

TABLE II: **Functional groups present in filtered dataset.**

The filtered ThermoML dataset contained 245 distinct (molecule, temperature, pressure) conditions, spanning 45 unique compounds. The functional groups represented in these compounds (as identified by the program checkmol v0.5 [32]) is summarized here.

The largest density errors occur for 1,4-dioxane, 2,5,8-trioxanonane, 2-aminoethanol, dimethyl carbonate, formamide, and water. The absolute error on these poor predictions is on the order of 0.05 g/mL , which is substantially higher than the measurement error ($\leq 0.008 \text{ g/mL}$; see Fig. 5). We note that our benchmark uses a GAFF model for water, as our purpose is to test the AM1-BCC charges. For production simulations, however, it is advisable to use one of the parameterized water models.

2. Static dielectric constant

As a measure of the dielectric response, the static dielectric constant of neat liquids provides a critical benchmark of the accuracy electrostatic treatment in forcefield models. We therefore compare simulations against the measurements in our ThermoML extract (Fig. 2). Overall, we find the dielectric constants to be qualitatively reasonable, but with clear deviations from experiment particularly for non-polar liquids having low static dielectric constants. This is not surprising given the complete neglect of electronic polarization which will be the dominant contribution for such liquids. In particular, GAFF/AM1-BCC systematically underestimates the dielectric constants for nonpolar organics, with the predictions of $\epsilon \approx 1.0 \pm 0.05$ being substantially smaller than the measured $\epsilon \approx 2$. Because this deviation likely stems from the lack of an explicit treatment of electronic polar-

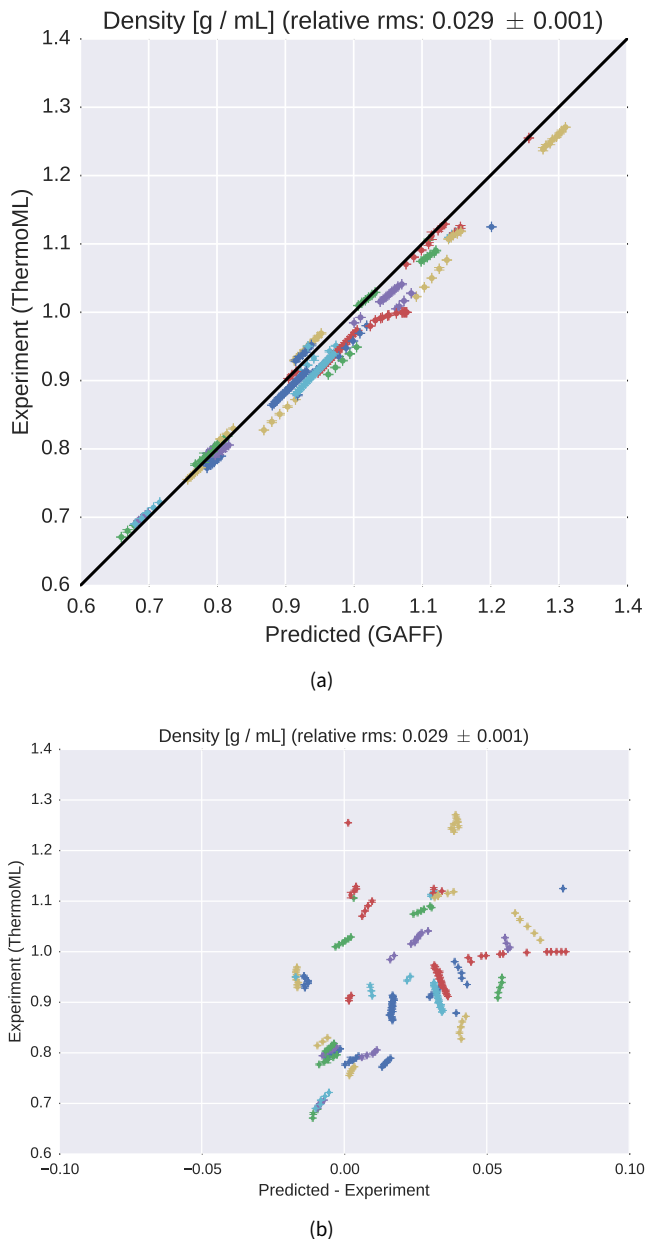

FIG. 1: **Comparison of liquid densities between experiment and simulation.** (a). Liquid density measurements extracted from ThermoML are compared against densities predicted using the GAFF / AM1-BCC small molecule fixed-charge forcefield. Color groupings represent identical chemical species. Simulation error bars represent one standard error of the mean, with the number of effective (uncorrelated) samples estimated using pymbar. Experimental error bars indicate the standard deviation between independently reported measurements, when available, or author-reported standard deviations in ThermoML entries; for some measurements, neither uncertainty estimate is available. See Fig. 5 for further discussion of error. (b). The same plot, but with the residual (predicted minus experiment) on the x axis.

ization, we used a simple empirical polarization model that computes the molecular electronic polarizability α as a sum of elemental atomic polarizability contributions [35].

From the computed molecular electronic polarizability α , an additive correction to the simulation-derived static dielectric constant accounting for the missing electronic polarizability can be computed [9]

$$\Delta\epsilon = 4\pi N \frac{\alpha}{\langle V \rangle} \quad (3)$$

A similar polarization correction was used in the development of the TIP4P-Ew water model, where it had a minor effect [9] because almost all the high static dielectric constant for water comes from the configurational response of its strong dipole. However, the missing polarizability is a dominant contribution to the static dielectric constant of nonpolar organic molecules; in the case of water, the empirical atomic polarizability model predicts a dielectric correction of 0.52, while 0.79 was used for the TIP4P-Ew model. Averaging all liquids in the present work leads to polarizability corrections to the static dielectric of 0.74 ± 0.08 .

IV. DISCUSSION

A. Mass densities

Our simulations have indicated the presence of systematic density biases with magnitudes larger than the measurement error. Correcting these errors may be a low-hanging fruit for future forcefield refinements. As an example of the feasibility of improved accuracy in densities, a recent three-point water model was able to recapitulate water density with errors of less than 0.005 g / mL over temperature range [280 K, 320 K] [38]. This improved accuracy in density prediction was obtained alongside accurate predictions of other experimental observables, including static dielectric constant. We suspect that such accuracy might be obtainable for GAFF-like forcefields across some portion of chemical space. A key challenge for the field is to demarcate the fundamental limit of fixed-charge forcefields for predicting orthogonal classes of experimental observables. For example, is it possible to achieve a relative density error of 10^{-4} without sacrificing accuracy of other properties such as enthalpies? In our opinion, the best way to answer such questions is to systematically build forcefields with the goal of predicting various properties to within their known experimental uncertainties, similar to what has been done for water [9, 38].

B. Dielectric constants in forcefield parameterization

A key feature of the static dielectric constant for a liquid is that, for forcefield purposes, it consists of two very different components, distinguished by the dependence on the fixed charges of the forcefield and dynamic motion of the molecule. One component, the high-frequency dielectric

FIG. 2: **Measured (ThermoML) versus predicted (GAFF / AM1-BCC) inverse static dielectrics (a).** Simulation error bars represent one standard error of the mean estimated via circular block averaging [36] with block sizes automatically selected to maximize the error [37].

Experimental error bars indicate the larger of standard deviation between independently reported measurements and the authors reported standard deviations; for some measurements, neither uncertainty estimate is available.

See Fig. 5 for further discussion of error. The inverse dielectric constant ϵ^{-1} is plotted instead of ϵ because ϵ^{-1} is directly proportional to the Coulomb interaction energy between point charges embedded in a dielectric material [e.g. $U(r) \propto q_1 q_2 / r \propto \epsilon^{-1}$].

constant, arises from the almost-instantaneous electronic polarization in response to the external electric field: this contributes a small component, generally around $\epsilon = 2$, which can be dominant for non-polar liquids but is completely neglected by the non-polarizable forcefields in common use for biomolecular simulations. The other component arises from the dynamical response of the molecule, through nuclear motion, to allow its various molecular multipoles to respond to the external electric field: for polar liquids such as water, this contributes the majority of the dielectric constant. Thus for polar liquids, having a high static dielectric constant, we expect the parameterized atomic charges to play a major role in the static dielectric.

Recent forcefield development has seen a resurgence of papers fitting dielectric constants during forcefield parameterization [11, 38]. However, a number of authors have pointed out potential challenges in constructing self-consistent fixed-charge forcefields [39, 40].

Interestingly, recent work by Dill and coworkers [39] observed that, for CCl_4 , reasonable choices of point charges

FIG. 3: Typical experimental static dielectric constants of some nonpolar compounds. (a). Measured static dielectric constants of various nonpolar or symmetric molecules [41, 42]. Fixed-charge forcefields give $\epsilon \approx 1$ for each species; for example, we calculated $\epsilon = 1.0030 \pm 0.0002$ for octane. (b). A congeneric series of chloro-substituted methanes have static dielectric constants between 2 and 13. Reported dielectric constants are at near-ambient temperatures.

are incapable of recapitulating the observed dielectric of $\epsilon = 2.2$, instead producing dielectric constants in the range of $1.0 \leq \epsilon \leq 1.05$. This behavior is quite general: fixed point charge forcefields will predict $\epsilon \approx 1$ for many nonpolar or symmetric molecules, but the measured dielectric constants are instead $\epsilon \approx 2$ (Fig. 3). While this behavior is well-known and results from missing physics of polarizability, we suspect it may have several profound consequences, which we discuss below.

Suppose, for example, that one attempts to fit force-field parameters to match the static dielectric constants of CCl₄, CHCl₃, CH₂Cl₂, and CH₃Cl. In moving from the tetrahedrally-symmetric CCl₄ to the asymmetric CHCl₃, it suddenly becomes possible to achieve the observed dielectric constant of 4.8 by an appropriate choice of point charges. However, the model for CHCl₃ uses fixed point charges to account for *both* the permanent dipole moment and the electronic polarizability, whereas the CCl₄ model contains no treatment of polarizability. We hypothesize that this inconsistency in parameterization may lead to strange mismatches, where symmetric molecules (e.g. benzene and CCl₄) have qualitatively different properties than closely related asymmetric molecules (e.g. toluene and CHCl₃).

How important is this effect? We expect it to be important wherever we encounter the transfer of a polar molecule

(such as a peptide, native ligand, or a pharmaceutical small molecule) from a polar environment (such as the cytosol, interstitial fluid, or blood) into a non-polar environment (such as a biological membrane or non-polar binding site of an enzyme or receptor). Thus we expect this to be implicated in biological processes ranging from ligand binding to absorption and distribution within the body. To understand this conceptually, consider the transfer of a polar small-molecule transfer from the non-polar interior of a lipid bilayer to the aqueous and hence very polar cytosol. As a possible real-world example, we imagine that the missing atomic polarizability could be important in accurate transfer free energies involving low-dielectric solvents, such as the small-molecule transfer free energy from octanol or cyclohexane to water. The Onsager model for solvation of a dipole μ of radius a gives us a way to estimate the magnitude of error introduced by making an error $\Delta\epsilon$ the static dielectric constant of a solvent. The free energy of dipole solvation is given by this model as

$$\Delta G = -\frac{\mu^2}{a^3} \frac{\epsilon - 1}{2\epsilon + 1} \quad (4)$$

such that, for an error of $\Delta\epsilon$ departing from the true static dielectric constant ϵ , we find the error in solvation is

$$\Delta\Delta G = -\frac{\mu^2}{a^3} \left[\frac{(\epsilon + \Delta\epsilon) - 1}{2(\epsilon + \Delta\epsilon) + 1} - \frac{\epsilon - 1}{2\epsilon + 1} \right] \quad (5)$$

For example, the solvation of water ($a = 1.93 \text{ \AA}$, $\mu = 2.2 \text{ D}$) in a low dielectric medium such as tetrachloromethane or benzene ($\epsilon \sim 2.2$, but $\Delta\epsilon = -1.2$) gives an error of $\Delta\Delta G \sim -2 \text{ kcal/mol}$.

The ramifications can be relevant for quantities of interest to drug discovery projects. Consider the transfer of small druglike molecules from a nonpolar solvent (such as cyclohexane) to water, a property often measured to indicate the expected degree of lipophilicity of a compound. To estimate the magnitude of error expected, for each molecule in the latest (Feb. 20) FreeSolv database [13, 43], we estimated the expected error in computed transfer free energies should GAFF/AM1-BCC be used to model the nonpolar solvent cyclohexane using the Onsager model (Eq. 5). We used took the cavity radius a to be the half the maximum interatomic distance and calculated $\mu = \sum_i q_i r_i$ using the provided mol2 coordinates and AM1-BCC charges. This calculation predicts a mean error of $-0.91 \pm 0.07 \text{ kcal/mol}$ for the 643 molecules (where the standard error is computed from bootstrapping over FreeSolv compound measurements), suggesting that the missing atomic polarizability unrepresentable by fixed point charge forcefields could contribute substantially to errors in predicted transfer and solvation properties of druglike molecules. We conjecture that this missing physics will be important in the upcoming (2015) SAMPL challenge [44], which will examine transfer free energies in several low dielectric media.

Given their ease of measurement and direct connection to long-range electrostatic interactions, static dielectric constants have high potential utility as primary data for force-field parameterization efforts. Although this will require the

use of forcefields with explicit treatment of atomic polarizability, the inconsistency of fixed-charge models in low-dielectric media is sufficiently alarming to motivate further study of polarizable forcefields. In particular, continuum methods [45–47], point dipole methods [48, 49], and Drude methods [50, 51] have been maturing rapidly. Finding the optimal balance of accuracy and performance remains an open question; however, the use of experimentally-parameterized direct polarization methods [52] may provide polarizability physics at a cost not much greater than fixed charge forcefields.

C. ThermoML as a data source

The present work has focused on the neat liquid density and dielectric measurements present in the ThermoML Archive [15, 53, 54] as a target for molecular dynamics forcefield validation. While liquid mass densities and static dielectric constants have already been widely used in forcefield work, several aspects of ThermoML make it a unique resource for the forcefield community. First, the aggregation, support, and dissemination of ThermoML datasets through the ThermoML Archive is supported by NIST, whose mission makes these tasks a long-term priority. Second, the ThermoML Archive is actively growing, through partnerships with several journals, and new experimental measurements published in these journals are critically examined by the TRC and included in the archive. Finally, the files in the ThermoML Archive are portable and machine readable via a formal XML schema, allowing facile access to hundreds of thousands of measurements. Numerous additional physical properties contained in ThermoML—including activity coefficients, diffusion constants, boiling point temperatures, critical pressures and densities, coefficients of expansion, speed of sound measurements, viscosities, excess molar enthalpies, heat capacities, and volumes—for neat phases and mixtures represent a rich dataset of high utility for forcefield validation and parameterization.

V. CONCLUSIONS

High quality, machine-readable datasets of physicochemical measurements will be required for the construction of next-generation small molecule forcefields. Here we have discussed the NIST/TRC ThermoML archive as a growing source of physicochemical measurements that may be useful for the forcefield community. From the NIST/TRC ThermoML archive, we selected a dataset of 245 ambient, neat liquid systems for which both densities and static dielectric constants are available. Using this dataset, we benchmarked GAFF/AM1-BCC, one of the most popular small molecule forcefields. We find systematic biases in densities and particularly static dielectric constants. Element-based empirical polarizability models are able to account for much of the systematic differences between GAFF/AM1-BCC and experiment, suggesting that non-polarizable force-

fields may show unacceptable biases in certain situations—possibly including the upcoming 2015 SAMPL challenge for transfer free energies.

FIG. 4: Dependence of computed density on simulation timestep.

To probe the systematic error from finite time-step integration, we examined the timestep dependence of butyl acrylate density. (a). The density is shown for several choices of timestep. (b). The relative error, as compared to the reference value, is shown for several choices of timestep. Error bars represent stand errors of the mean, with the number of effective samples estimated using pymbar's statistical inefficiency routine [30]. The reference value is estimated by linear extrapolation to 0 fs using the 0.5 fs and 1.0 fs data points; the linear extrapolation is shown as black lines. We find a 2 fs timestep leads to systematic biases in the density on the order of 0.13%, while 1 fs reduces the systematic bias to approximately 0.08%—we therefore selected a 1 fs timestep for the present work, where we aimed to achieve three digits of accuracy in density predictions.

FIG. 5: Assessment of experimental error: Density To assess the experimental error in our ThermoML extract, we compared three difference estimates of uncertainty. In the first approach (Weighted), we computed the standard deviation of the optimally weighted average of the measurements, using the uncertainties reported by authors ($\sigma_{Weighted} = [\sum_k \sigma_k^{-2}]^{-0.5}$). This uncertainty estimator places the highest weights on measurements with small uncertainties and is therefore easily dominated by small outliers and uncertainty under-reporting. In the second approach (Median), we estimated the median of the uncertainties reported by authors; this statistic should be robust to small and large outliers of author-reported uncertainties. In the third approach (Std), we calculated at the standard deviation of independent measurements reported in the ThermoML extract, completely avoiding the author-reported uncertainties. Plot (a) compares the three uncertainty estimates. We see that author-reported uncertainties appear to be substantially smaller than the scatter between the observed measurements. A simple psychological explanation might be that because density measurements are more routine, the authors simply report the accuracy limit of their hardware (e.g. 0.0001 g / mL for a Mettler Toledo DM40 [55]). However, this hardware limit is not achieved due to inconsistencies in sample preparation; see Appendix in Ref. [56]. Panel (b) shows the same information as (a) but as a function of the measurement index, rather than as a scatter plot—because not all measurements have author-supplied uncertainties, panel (c) contains slightly more data points than (a, b).

(b)

FIG. 6: Assessment of experimental error: Static Dielectric Constant To assess the experimental error in our ThermoML extract, we compared three difference estimates of uncertainty. In the first approach (Weighted), we computed the standard deviation of the optimally weighted average of the measurements, using the uncertainties reported by authors ($\sigma_{Weighted} = [\sum_k \sigma_k^{-2}]^{-0.5}$). This uncertainty estimator places the highest weights on measurements with small uncertainties and is therefore easily dominated by small outliers and uncertainty under-reporting. In the second approach (Median), we estimated the median of the uncertainties reported by authors; this statistic should be robust to small and large outliers of author-reported uncertainties. In the third approach (Std), we calculated at the standard deviation of independent measurements reported in the ThermoML extract, completely avoiding the author-reported uncertainties. Plot (a) compares the three uncertainty estimates. Unlike the case of densities, author-reported uncertainties appear to be somewhat larger than the scatter between the observed measurements. Panel (b) shows the same information as (a) but as a function of the measurement index, rather than as a scatter plot—because not all measurements have author-supplied uncertainties, panel (c) contains slightly more data points than (a, b).

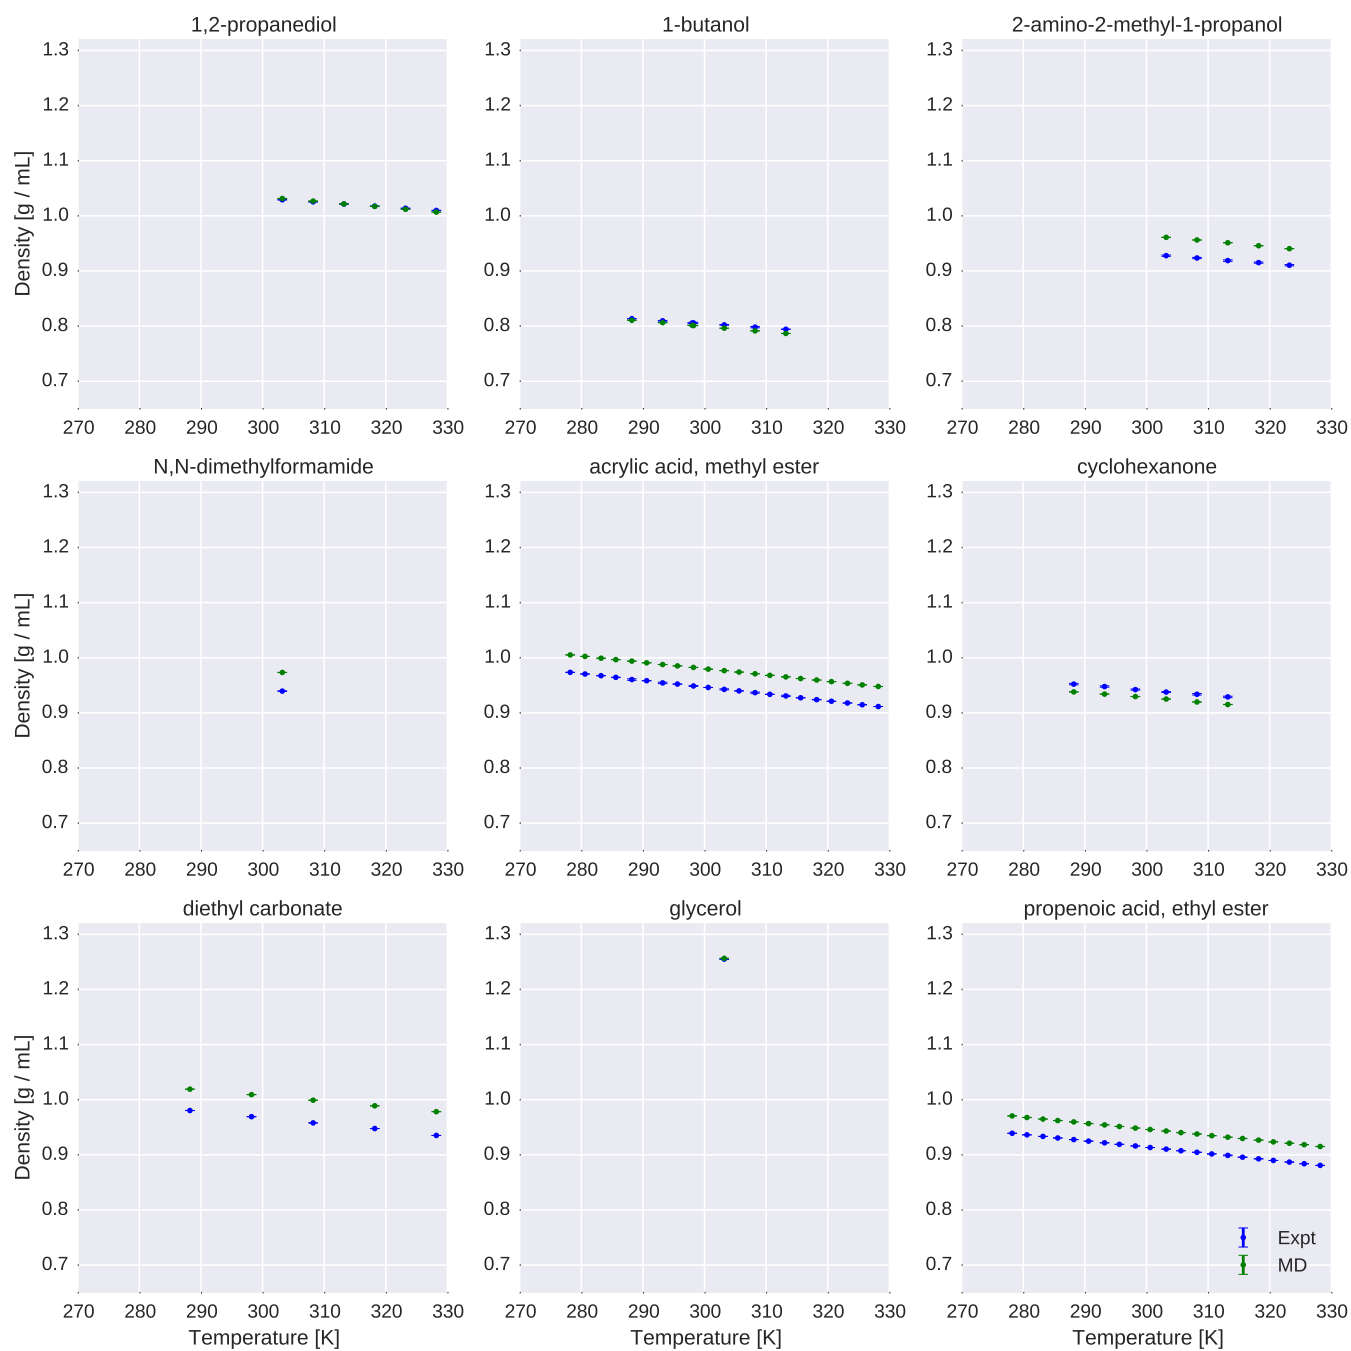

FIG. 7: **Comparison of simulated and experimental densities for all compounds.** Measured (blue) and simulated (green) densities are shown in units of g / mL.

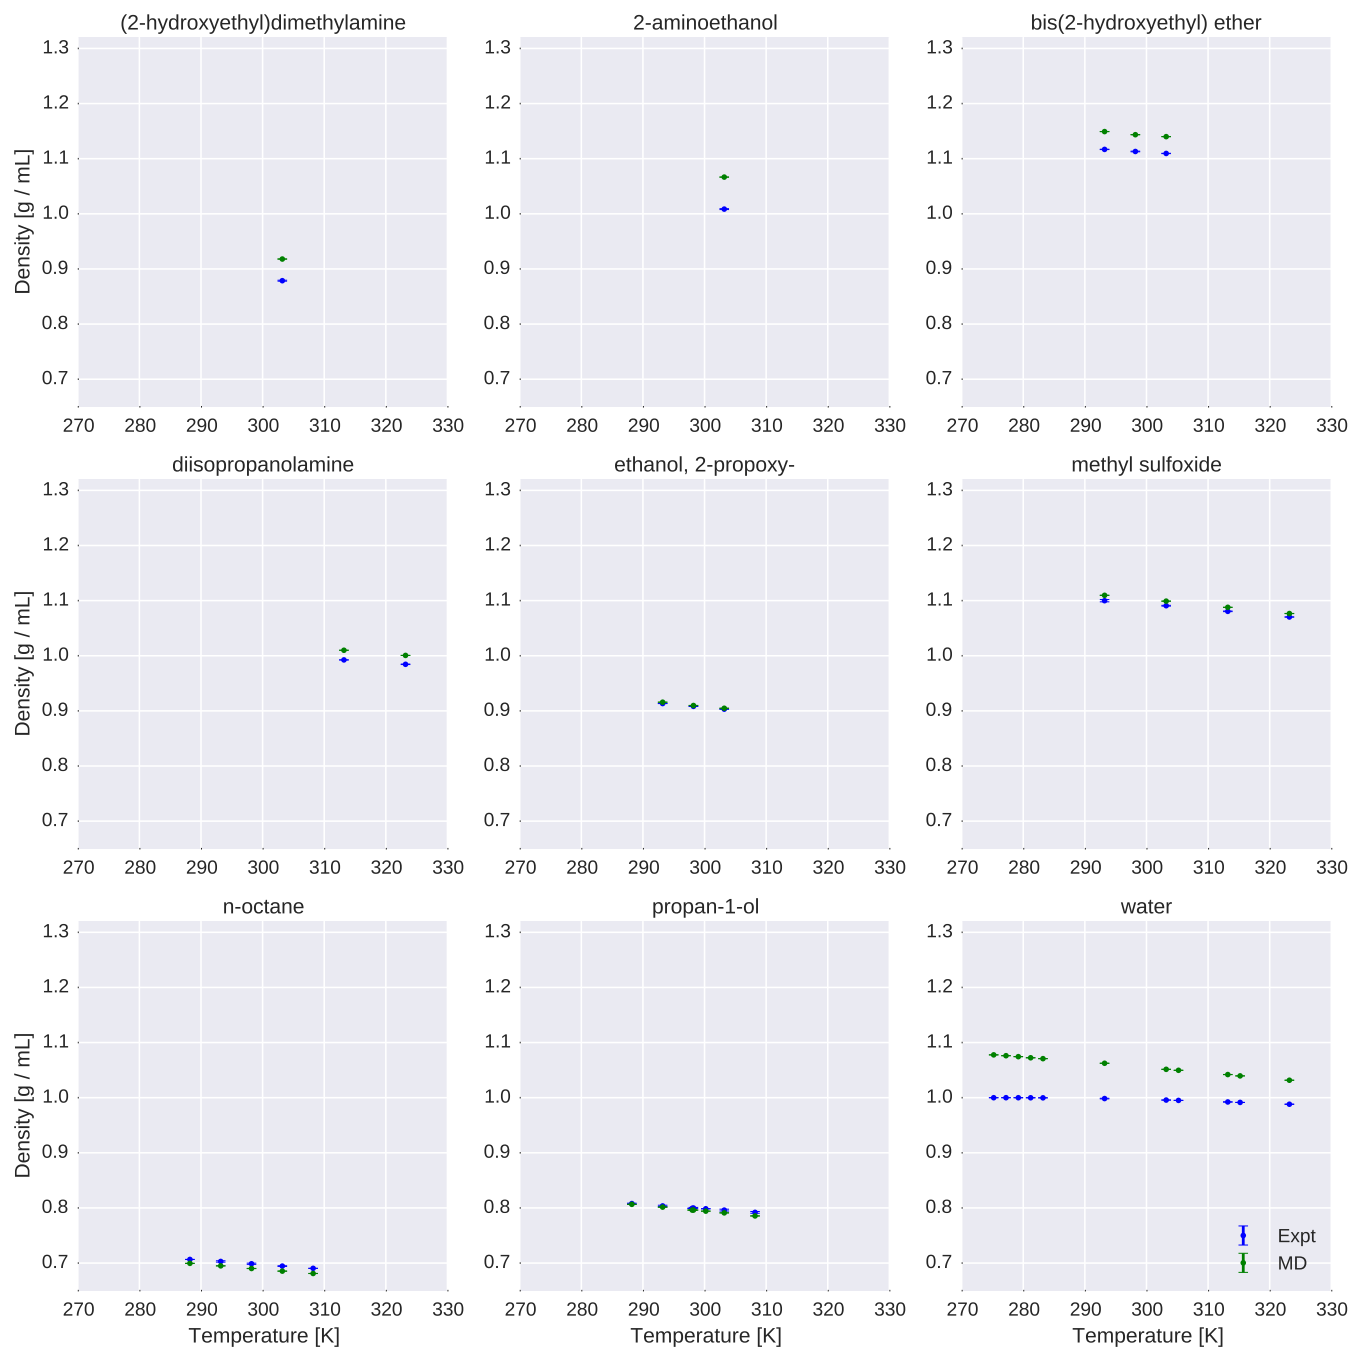

FIG. 7: **Comparison of simulated and experimental densities for all compounds.** Measured (blue) and simulated (green) densities are shown in units of g / mL.

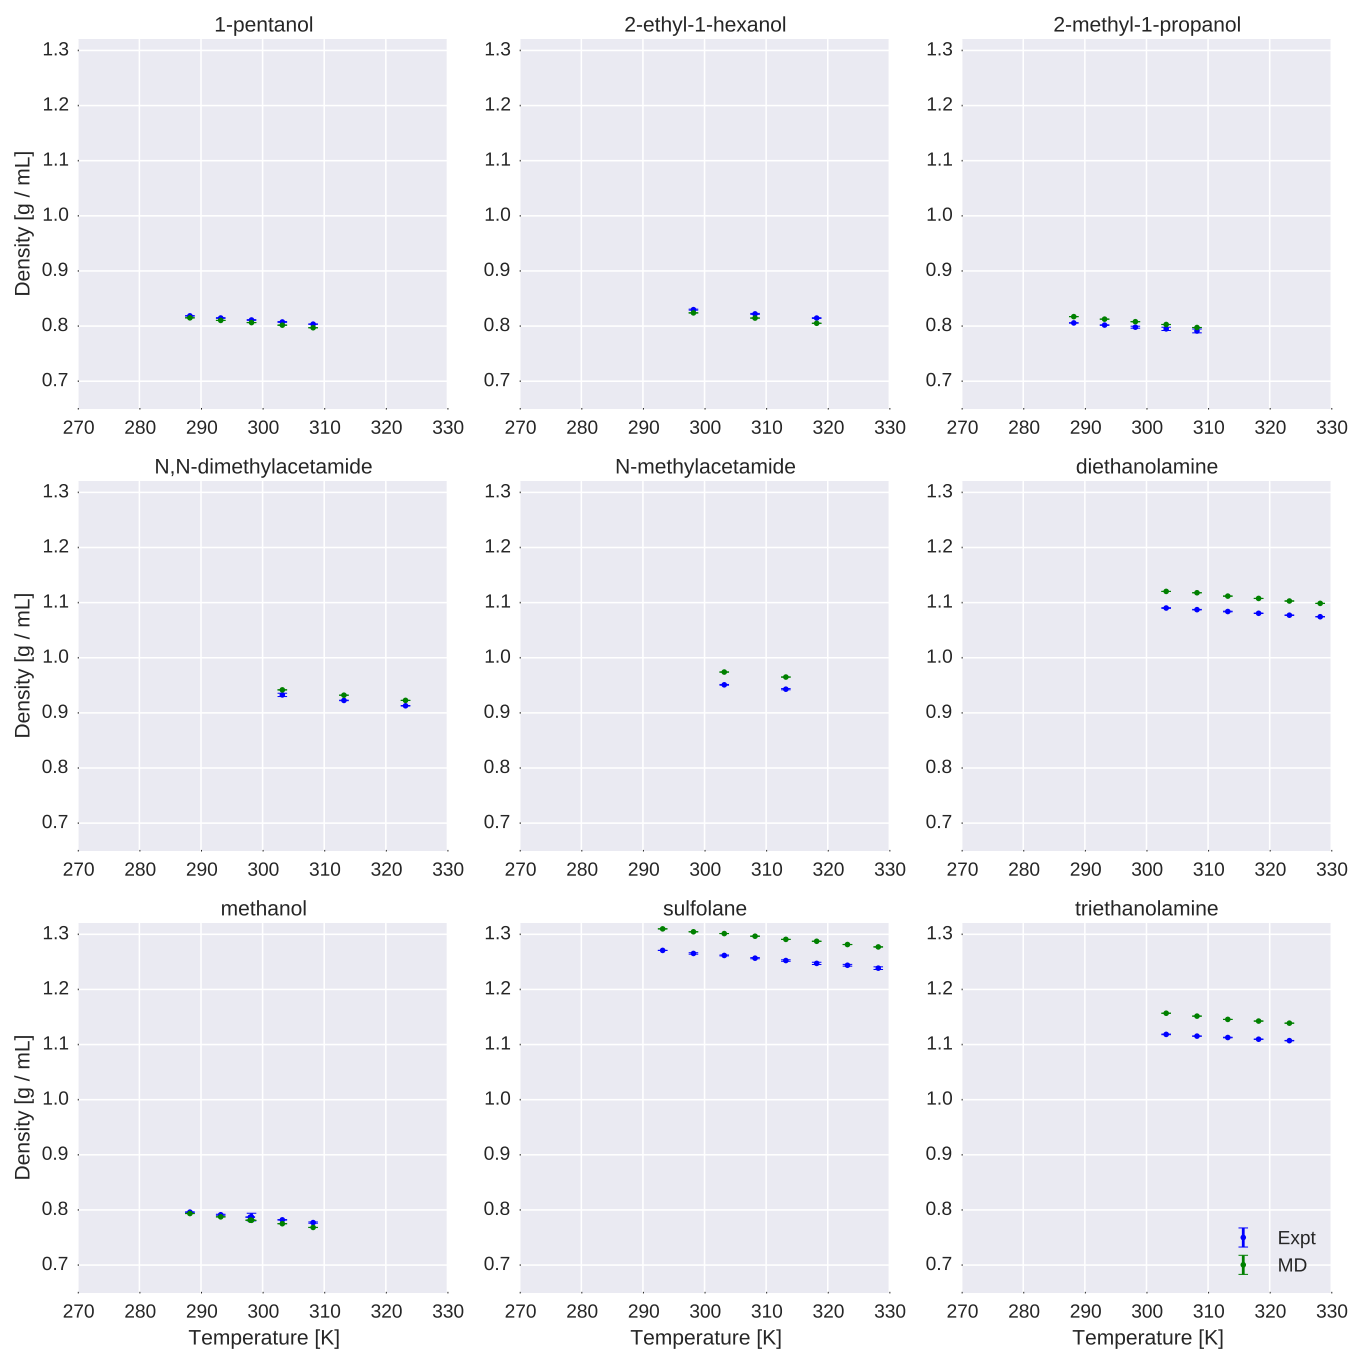

FIG. 7: **Comparison of simulated and experimental densities for all compounds.** Measured (blue) and simulated (green) densities are shown in units of g / mL.

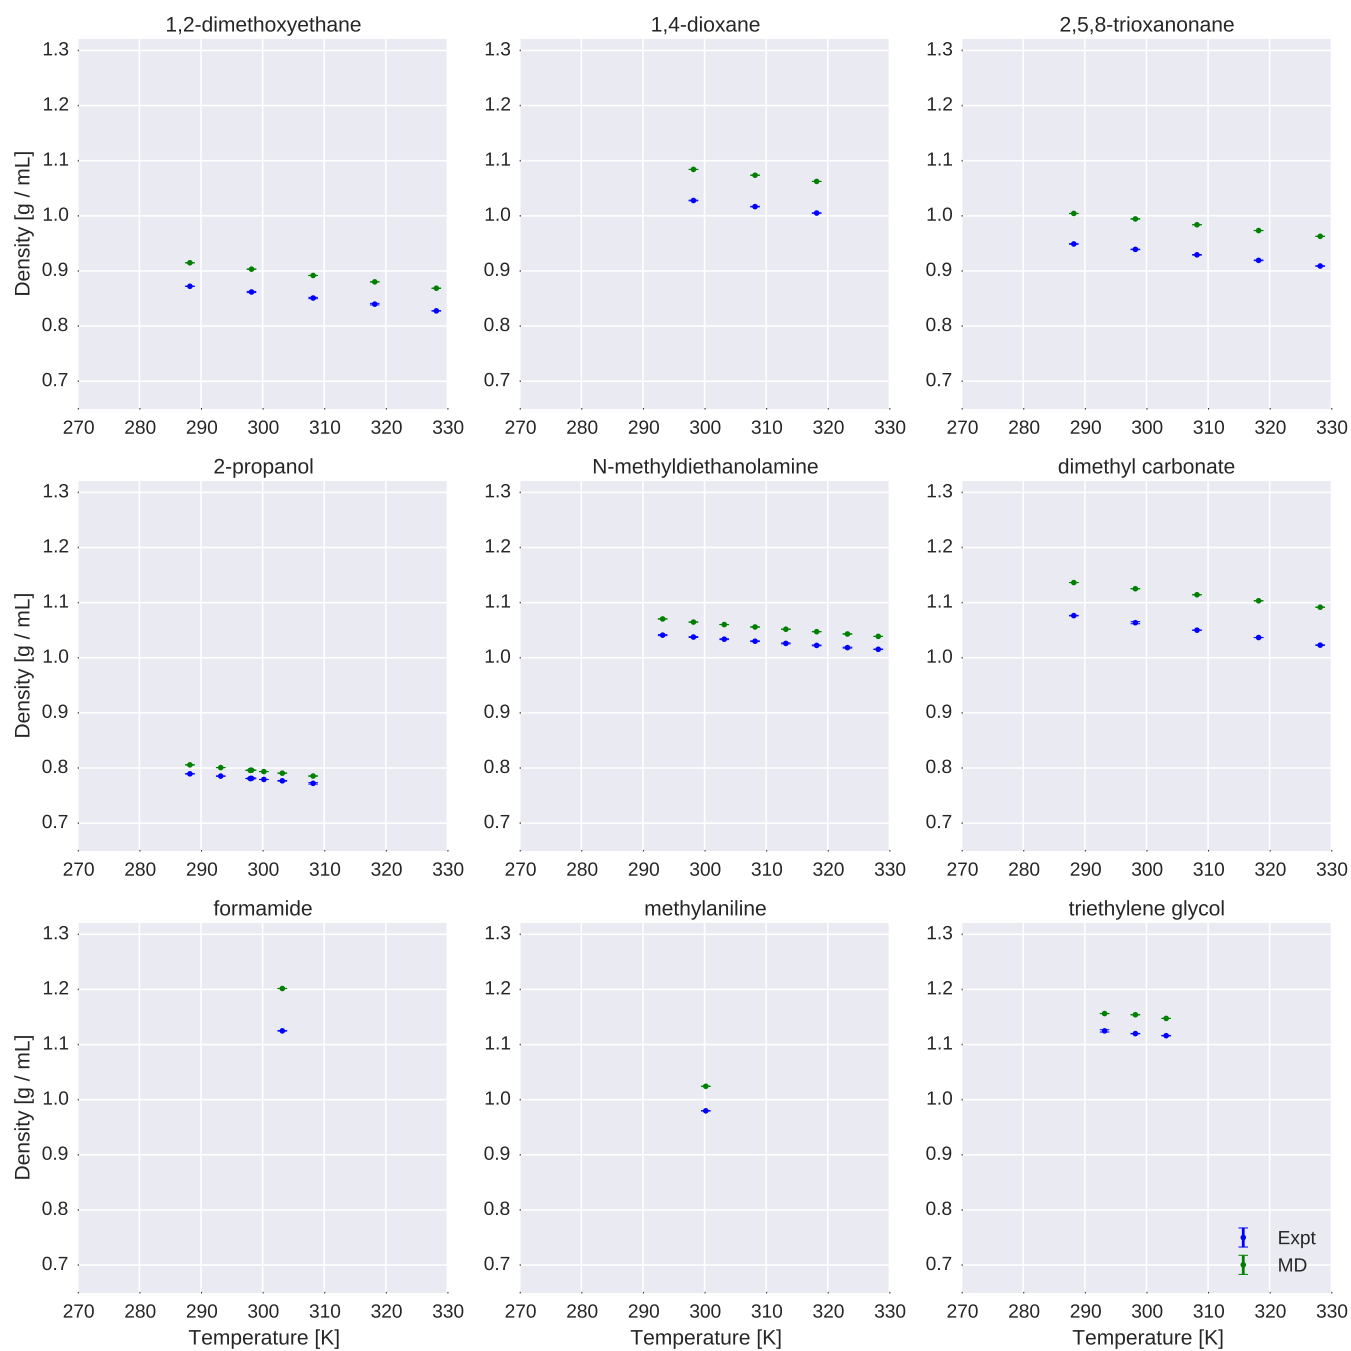

FIG. 7: **Comparison of simulated and experimental densities for all compounds.** Measured (blue) and simulated (green) densities are shown in units of g / mL.

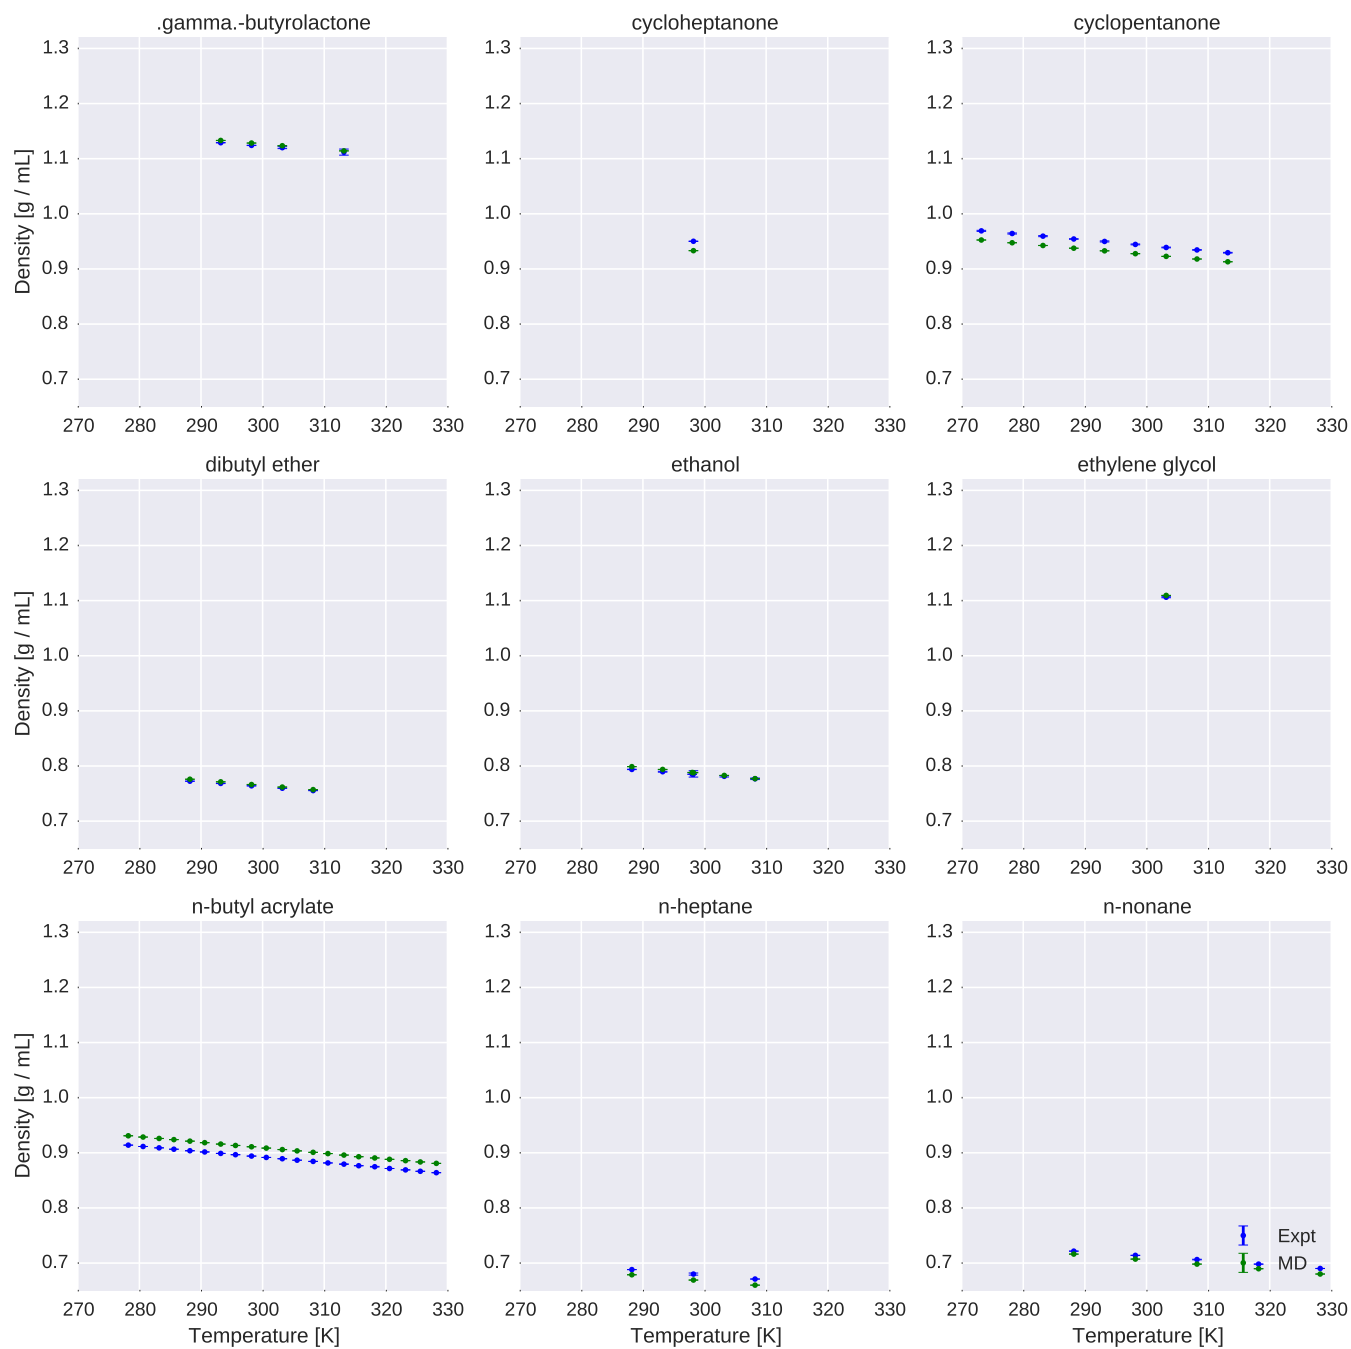

FIG. 7: **Comparison of simulated and experimental densities for all compounds.** Measured (blue) and simulated (green) densities are shown in units of g / mL.

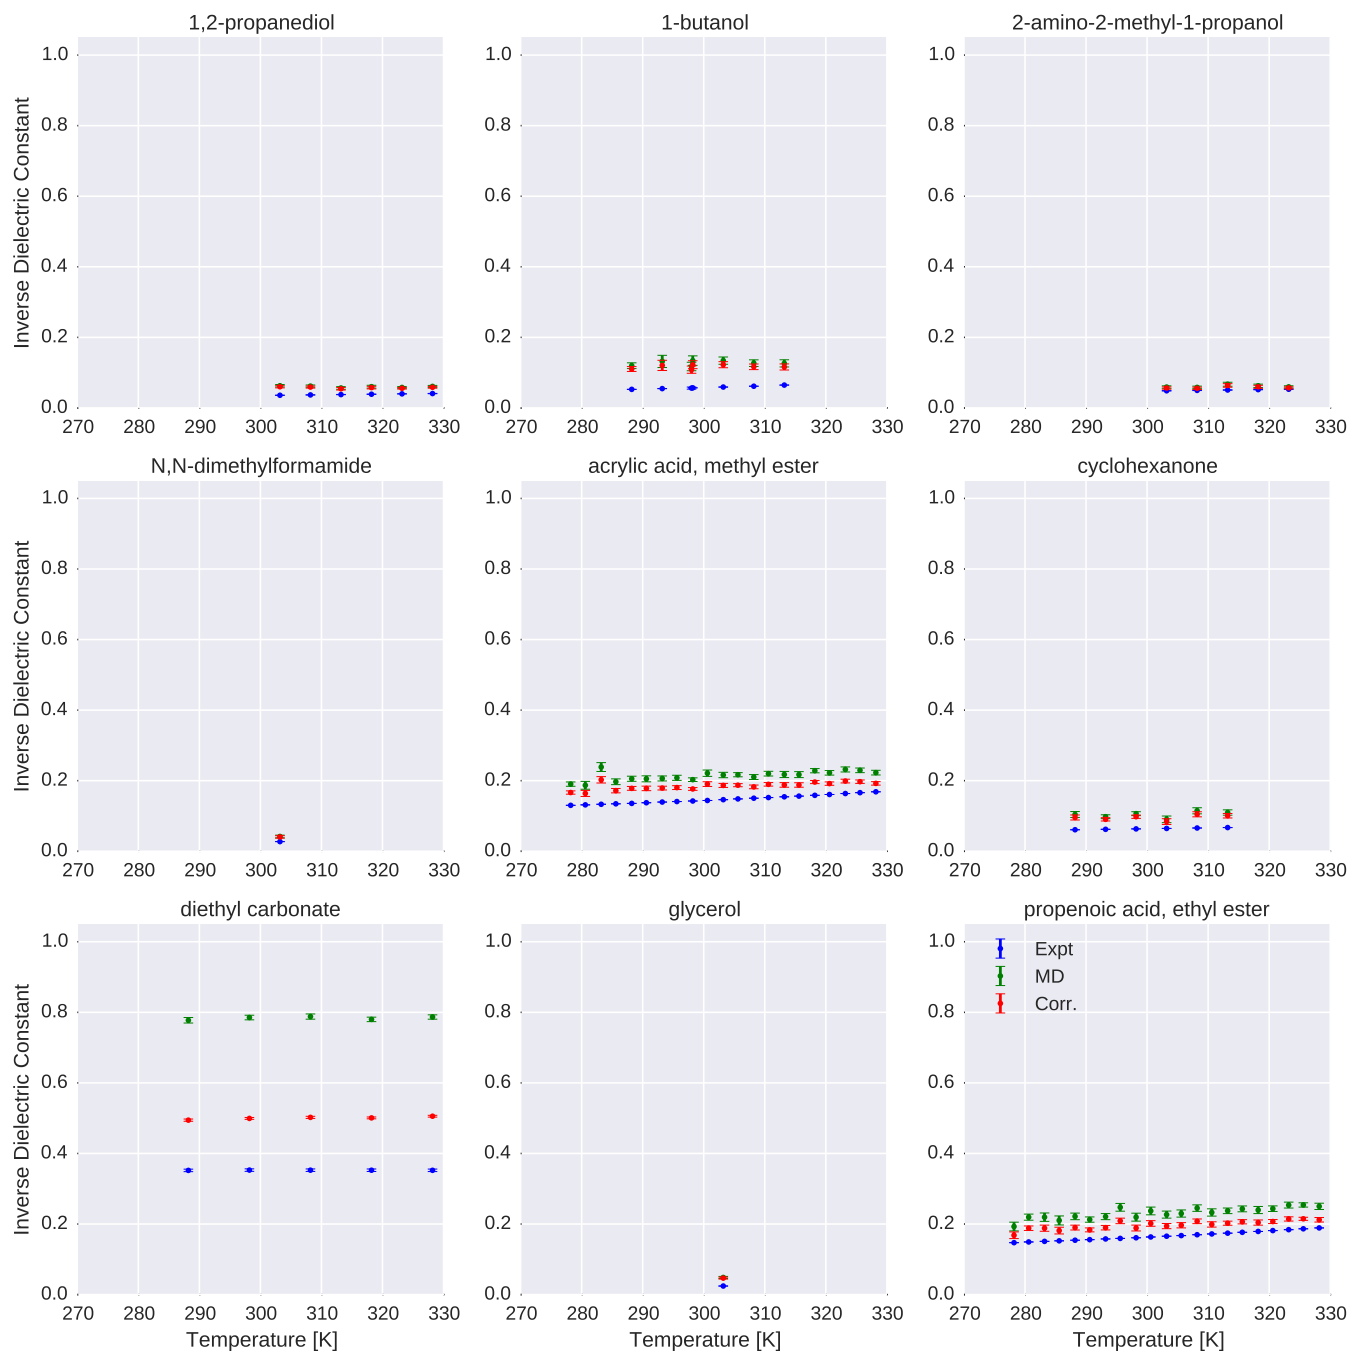

FIG. 8: Comparison of simulated and experimental static dielectric constants for all compounds. Measured (blue), simulated (green), and polarizability-corrected simulated (red) static dielectric constants are shown for all compounds.

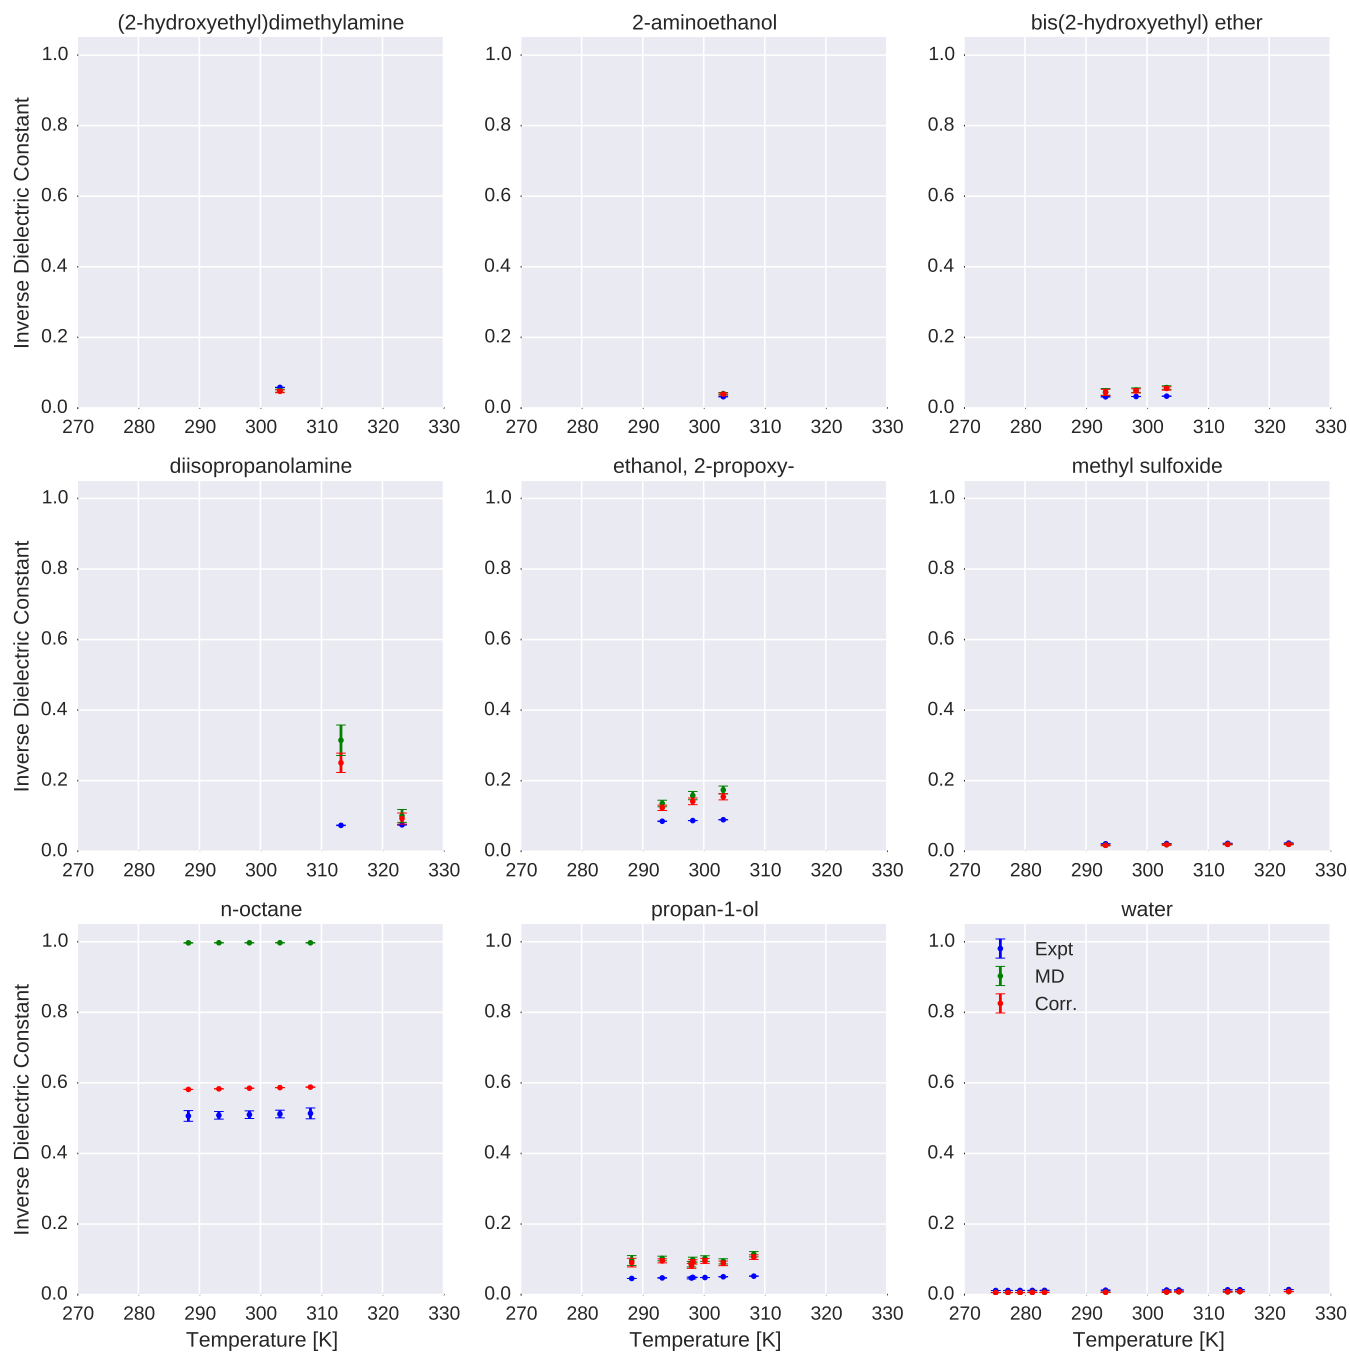

FIG. 8: **Comparison of simulated and experimental static dielectric constants for all compounds.** Measured (blue), simulated (green), and polarizability-corrected simulated (red) static dielectric constants are shown for all compounds.

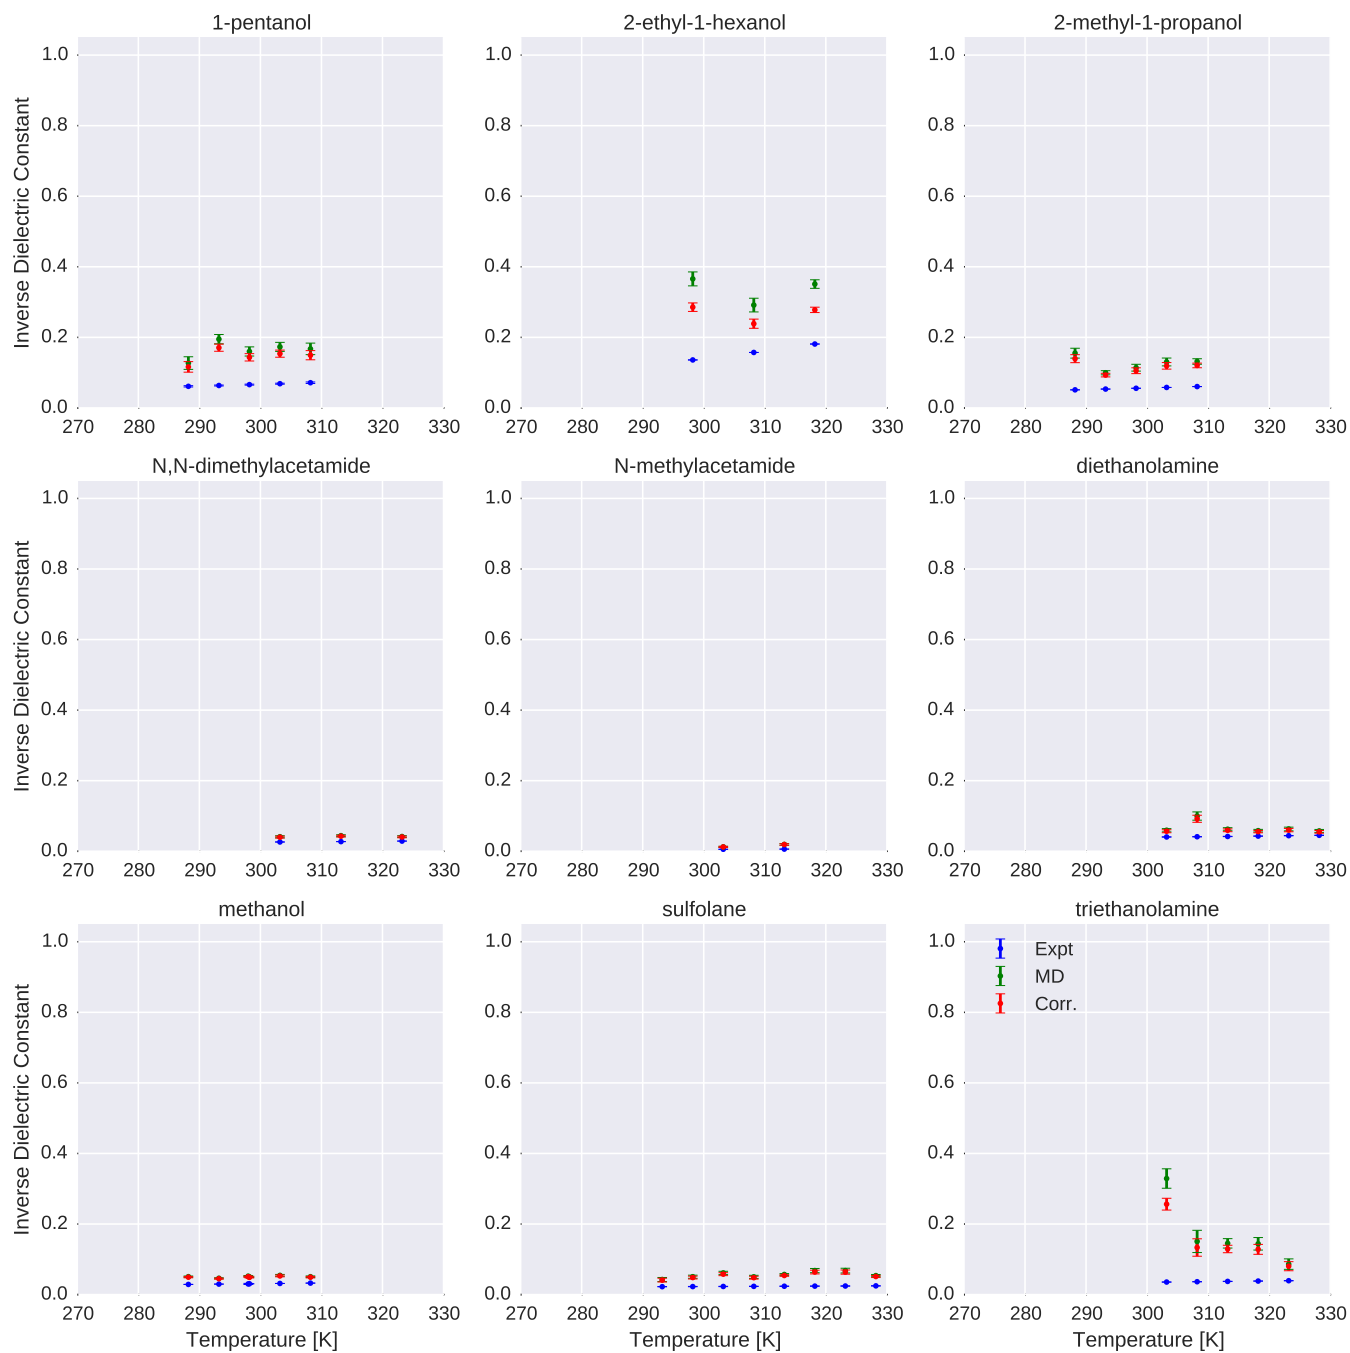

FIG. 8: **Comparison of simulated and experimental static dielectric constants for all compounds.** Measured (blue), simulated (green), and polarizability-corrected simulated (red) static dielectric constants are shown for all compounds.

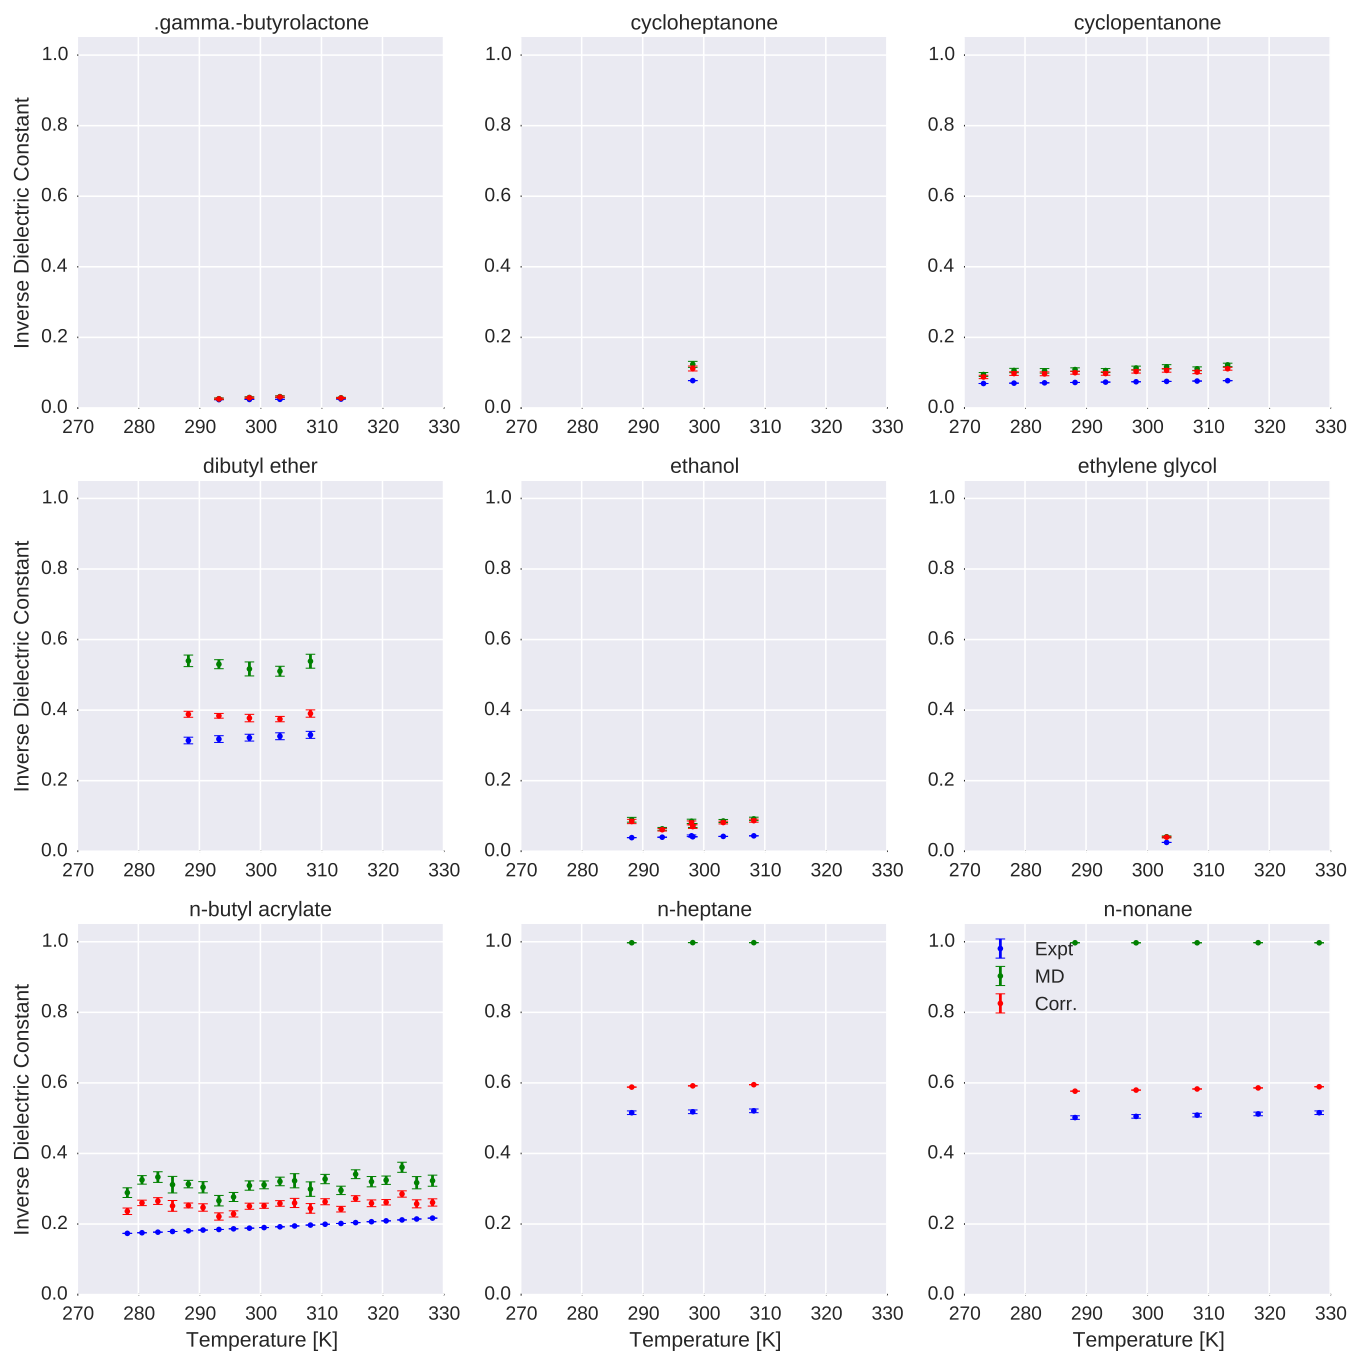

FIG. 8: Comparison of simulated and experimental static dielectric constants for all compounds. Measured (blue), simulated (green), and polarizability-corrected simulated (red) static dielectric constants are shown for all compounds.

1. Dependency Installation

The following shell commands can be used to install the necessary prerequisites via the conda package manager for Python:

```
$ conda config --add channels http://conda.binstar.org/omnia
$ conda install "gaff2xml==0.6.4" "pymbar==2.1" "mdtraj==1.3" "openmm==6.3" packmol
%
```

Note that this command installs the exact versions used in the present study. However, for authors interested in extending the present work, we suggest using the most up-to-date versions available instead, which involves replace the equality symbols == with >=.
