Atomistic molecular simulations are a powerful way to make quantitative predictions, but the accuracy of these predictions depends entirely on the quality of the forcefield employed. While experimental measurements of fundamental physical properties offer a straightforward approach for evaluating forcefield quality, the bulk of this information has been tied up in formats that are not machine-readable. Compiling benchmark datasets of physical properties from non-machine-readable sources require substantial human effort and is prone to accumulation of human errors, hindering the development of reproducible benchmarks of forcefield accuracy. Here, we examine the feasibility of benchmarking atomistic forcefields against the NIST ThermoML data archive of physicochemical measurements, which aggregates thousands of experimental measurements in a portable, machine-readable, self-annotating format. As a proof of concept, we present a detailed benchmark of the generalized Amber small molecule forcefield (GAFF) using the AM1-BCC charge model against measurements (specifically bulk liquid densities and static dielectric constants at ambient pressure) automatically extracted from the archive, and discuss the extent of available data. The results of this benchmark highlight a general problem with fixed-charge forcefields in the representation low dielectric environments such as those seen in binding cavities or biological membranes.

Keywords: molecular mechanics forcefields; forcefield parameterization; forcefield accuracy; forcefield validation; mass density; static dielectric constant; biomolecular simulation

I. INTRODUCTION

Recent advances in hardware and software for molecular dynamics simulation now permit routine access to atomistic simulations at the 100 ns timescale and beyond [1]. Leveraging these advances in combination with consumer GPU clusters, distributed computing, or custom hardware has brought microsecond and millisecond simulation timescales within reach of many laboratories. These dramatic advances in sampling, however, have revealed deficiencies in forcefields as a critical barrier to enabling truly predictive simulations of physical properties of biomolecular systems.

Protein and water forcefields have been the subject of numerous benchmarks [2–4] and enhancements [5–7], with key outcomes including the ability to fold fast-folding proteins [8–10], improved fidelity of water thermodynamic properties [11], and improved prediction of NMR observables. Although small molecule forcefields have also been the subject of benchmarks [12] and improvements [13], such work has typically focused on small perturbations to specific

functional groups. For example, a recent study found that modified hydroxyl nonbonded parameters led to improved prediction of static dielectric constants and hydration free energies [13]. There are also outstanding questions of generalizability of these targeted perturbations; it is uncertain whether changes to the parameters for a specific chemical moiety will be compatible with seemingly unrelated improvements to other groups. Addressing these questions requires establishing community agreement upon shared benchmarks that can be easily replicated among laboratories to test proposed forcefield enhancements and exapanded as the body of experimental data grows.

A key barrier to establishing reproducible and extensible forcefield accuracy benchmarks is that many experimental datasets are heterogeneous, paywalled, and unavailable in machine-readable formats (although notable counterexamples exist, e.g. the RCSB [14], FreeSolv [15], and the BMRB [16]). While this inconvenience is relatively minor for benchmarking forcefield accuracy for a single target system (e.g. water), it becomes prohibitive for studies spanning the large relevant chemical spaces, such as forcefields intended to describe a large variety of druglike small organic molecules.

In addition to inconvenience, the number and kind of human-induced errors that can corrupt hand-compiled benchmarks are legion. A United States Geological Survey (USGS) case study examining the reporting and use of literature values of the aqueous solubility (S_w) and octanolowater partition coefficients (K_{ow}) for DDT and its persis-

61 tent metabolite DDE provides incredible insight into a va- 115 described in Section III A were applied. riety of common errors [17]. Secondary sources are often cited as primary sources—a phenomenon that occurred up to five levels deep in the case of DDT/DDE; citations for 116 data are often incorrect, misattributed to unrelated publications, or omitted altogether; numerical data can be mistranscribed, transposed, or incorrectly converted among unit systems [17]. This occurs to such a degree that the authors note "strings of erroneous data compose as much as 41–73 percent of the total data" [17]. Given the incredible importance of these properties for human health and the environment, the quality of physicochemical datasets of far lesser importance is highly suspect.

To ameliorate problems of data archival, the NIST Thermodynamics Research Center (TRC) has developed an IUPAC standard XML-based format—ThermoML [18-20]—for storing physicochemical measurements, uncertainties, and metadata. Manuscripts containing new experimental measurements submitted to several journals (J. Chem. Eng. Data, J. Chem. Therm., Fluid Phase Equil., Therm. Acta, and Int. J. Therm.) are guided through a data archival process that involves sanity checks, conversion to a standard machine-readable format, and archival at the TRC (http://trc.nist.gov/ThermoML.html).

Here, we examine the ThermoML archive as a potential source for a reproducible, extensible accuracy benchmark of biomolecular forcefields. In particular, we concentrate on two important physical property measurements easily computable in many simulation codes—neat liquid density and static dielectric constant measurements—with the goal of developing a standard benchmark for validating these properties in fixed-charge forcefields of drug-like molecules and biopolymer residue analogues. These two properties provide sensitive tests of forcefield accuracy that are nonetheless straightforward to calculate. Using these data, we evaluate the generalized Amber small molecule forcefield (GAFF) [21, 22] with the AM1-BCC charge model [23, 24] and 98 identify systematic biases to aid further forcefield refinement.

METHODS

100

101

A. ThermoML Archive retrieval and processing

A tarball archive snapshot of the ThermoML Archive was obtained from the the NIST TRC on 8 Apr. To explore the content of this archive, we created a Python (version 2.7.9) tool (ThermoPyL: https://github.com/choderalab/ThermoPyL) formats the XML content into a spreadsheet-like format accessible via the Pandas (version 0.15.2) library. First, we obtained the XML schema (http://media.iupac. org/namespaces/ThermoML/ThermoML.xsd) defining the layout of the data. This schema was converted into a Python object via PyXB 1.2.4 (http://pyxb.sourceforge.net/). 161 ₁₁₃ Finally, this schema was used to extract the data into ₁₆₂ algorithm [36] and equilibrated for 10^7 steps with an equili- $_{114}$ Pandas [25] dataframes, and the successive data filters $_{163}$ bration timestep of 0.4 fs and a collision rate of 5 ps $^{-1}$. Pro-

Simulation

To enable automated accuracy benchmarking of physicochemical properties of neat liquids such as mass density and dielectric constant, we developed a semi-automated pipeline for preparing simulations, running them on a stan-121 dard computer cluster using a portable simulation package, and analyzing the resulting data. All code for this procedure is available at https://github.com/choderalab/ 124 LiquidBenchmark. Below, we describe the operation of the various stages of this pipeline and their application to the 126 benchmark reported here.

Preparation

Chemical names were parsed from the ThermoML extract 129 and converted to both CAS and smiles strings using cirpy 130 [26]. Smiles strings were converted into molecular struc-131 tures using the OpenEye Python Toolkit version 2015-2-3 132 [27], as wrapped in openmoltools.

Simulation boxes containing 1000 molecules were con-134 structed using PackMol version 14-225 [28, 29] wrapped in 135 the Python automation library openmoltools. In order to ensure stable automated equilibration, PackMol box volumes were chosen to accommodate twice volume of the enclosed atoms, with atomic radii estimated as 1.06 Å and 1.53 Å for 139 hydrogens and nonhydrogens, respectively.

For this illustrative benchmark, we utilized the generalized Amber small molecule forcefield (GAFF) [21, 22] with the AM1-BCC charge model [23, 24], which we shall refer to as the 143 GAFF/AM1-BCC forcefield.

Canonical AM1-BCC [23, 24, 30] charges were generated with the OpenEye Python Toolkit version 2015-2-3 [27], using 146 the oequacpac.OEAssignPartialCharges module with 147 the OECharges_AM1BCCSym option, which utilizes a conformational expansion procedure (using oeomega. OEOmega [31]) prior to charge fitting to minimize artifacts from in-150 tramolecular contacts. The OEOmega selected conformer using antechamber (with parmchk2) 152 and tleap in AmberTools 14 [32] to produce Amberformat prmtop and inperd files, which were then read 154 into OpenMM to perform molecular simulations using the 155 simtk.openmm.app module.

The simulations reported here used libraries open-157 moltools 0.6.4 [33], OpenMM 6.3 [34], and MDTraj 1.3 [35]. Exact commands to install various dependencies can be found in Appendix A 1.

Equilibration and production

Simulation boxes were first minimized using the L-BFGS

duction simulations were performed with OpenMM 6.3 [34] 217 using a Langevin Leapfrog integrator [37] (with collision rate ps⁻¹) and a 1 fs timestep, as we found that timesteps of 2 fs timestep or greater led to a significant timestep dependence in computed equilibrium densities (Fig. 4).

Equilibration and production simulations utilized a Monte Carlo barostat with a control pressure of 1 atm (101.325 kPa), utilizing molecular scaling and automated step size adjustment during equilibration, with volume moves attempted every 25 steps. The particle mesh Ewald (PME) method with conducting boundary conditions [38] was used with a longrange cutoff of 0.95 nm and a long-range isotropic dispersion correction. PME grid and spline parameters were automatically selected using the default settings in OpenMM 6.3 for the CUDA platform [34].

Automatic termination criteria. Production simulations were continued until automatic analysis showed standard errors in densities were less than 2×10^{-4} g / cm^3 . Automatic analysis of the production simulation data was run every 1 ns of simulation time, and utilized the detectEquilibration method in the timeseries module of pymbar 2.1 [39] to automatically discard the initial portion of the production simulation containing strong far-from-equilibrium behavior by maximizing the number of effectively uncorrelated samples in the remainder of the production simulation as determined by autocorrelation analysis using the fast adaptive statistical inefficiency computation method as implemented the timeseries.computeStatisticalInefficiency method of pymbar 2.1 (where the algorithm is described in [40]). This approach is essentially the same as the fixedwidth procedure described by eq. 7.12 of ref. [41], with n^* equal to 4000 and the sequential testing correction (n^{-1} term) ignored due to the large value of n. Statistical errors were computed by $\delta^2 \rho \approx {\rm v}ar(\rho)/N_{\rm eff}$, where ${\rm v}ar(\rho)$ is the sample variance of the density and $N_{
m eff}$ is the number of effectively uncorrelated samples. With this protocol, we found starting trajectory lengths of 12000 (8000, 16000) frames (250 fs each), discarded regions of 28 (0, 460), and statistical inefficiencies of 20 (15, 28); reported numbers indicate (median, (25%, 75%)).

Instantaneous densities were stored every 250 fs, while trajectory snapshots were stored every 5 ps.

C. Timings

207

The wall time required for a given simulation depends on 251 the number of atoms (3,000 - 29,000), the GPU used (GTX 680 or GTX Titan), and the time required for automated termination. For butyl acrylate (21,000 atoms) on a GTX Titan, 253 the wall-clock performance is approximately 80 ns / day. Us- 254 ThermoML Archive and performed a number of sequening 80 ns / day with approximately 3 ns of production simu- 255 tial filtering steps to produce an ThermoML extract relelation corresponds to 1 hour for the production segment of 256 vant for benchmarking forcefields describing small organic the simulation and 3 hours for the fixed equilibration portion 257 molecules. As our aim is to explore neat liquid data with of 10^7 steps.

Data analysis and statistical error estimation

Trajectory analysis was performed using OpenMM 6.3 [34] 219 and MDTraj 1.3 [35].

Mass density. Mass density ρ was computed via the rela-221 tion,

$$\rho = \left\langle \frac{M}{V} \right\rangle,\tag{1}$$

 $_{
m 222}$ where M is the total mass of all particles in the system and V is the instantaneous volume of the simulation box.

Static dielectric constants. Static dielectric constants 225 were calculated using the dipole fluctuation approach ap-226 propriate for PME with conducting ("tin-foil") boundary conditions [11, 42], with the total system box dipole μ computed from trajectory snapshots using MDTraj 1.3 [35].

$$\epsilon = 1 + \beta \frac{4\pi}{3} \frac{\langle \mu \cdot \mu \rangle - \langle \mu \rangle \cdot \langle \mu \rangle}{\langle V \rangle} \tag{2}$$

 $_{\mbox{\tiny 229}}$ where $\beta \equiv 1/k_BT$ is the inverse temperature.

Computation of expectations. Expectations were esti-₂₃₁ mated by computing sample means over the production 232 simulation after discarding the initial far-from-equilibrium portion to equilibration (as described in **Automatic termi-**234 **nation criteria** above).

Statistical uncertainties. For density uncertainties, 236 the Markov chain standard error (MCSE) was estimated as $\frac{\sigma}{\sqrt{N_{eff}}}$, where σ is the density standard deviation of the simulation not discarded to equilibration, $N_{eff}=rac{N}{g}$ is the ef- $_{239}$ fective sample size, and g is the statistical inefficiency as estimated from the density time series. For dielectric uncertainties, the portion of the production simulation not discarded to equilibration was used as input to a circular block bootstrapping procedure [43] with block sizes automatically selected to maximize the error [44].

Code availability

Data analysis, all intermediate data (except configurational trajectories, due to their large size), and figure cre-248 ation code for this work is available at https://github. 249 com/choderalab/LiquidBenchmark.

RESULTS

Extracting neat liquid measurements from the NIST TRC ThermoML Archive

As described in Section IIA, we retrieved a copy of the 258 functional groups relevant to biopolymers and drug-like

	Number of measurements remaining

tertiary aliphatic amine (trialkylamine)	3
tertiary amine	3

TABLE II: Functional groups present in filtered dataset.

The filtered ThermoML dataset contained 246 distinct (molecule, temperature, pressure) conditions, spanning 45 unique compounds. The functional groups represented in these compounds (as identified by the program checkmol v0.5 [45]) is summarized here.

Benchmarking GAFF/AM1-BCC against the ThermoML **Archive**

1. Mass density

Mass densities of bulk liquids have been widely used for parameterizing and testing forcefields, particularly the 296 Lennard-Jones parameters representing dispersive and re-₂₉₇ pulsive interactions [46, 47]. We therefore used the present ThermoML extract as a benchmark of the GAFF/AM1-BCC forcefield (Fig. 1).

Overall accuracy. Overall, the densities show reason-301 able accuracy, with a root-mean square (RMS) relative er- $_{302}$ ror over all measurements of (3.0 \pm 0.1)%, especially en-The temperature and pressure rounding step was motivated 303 couraging given that this forcefield was not designed with the intention of modeling bulk liquid properties of organic molecules [21, 22]. This is reasonably consistent with previand ambient pressure might be entered as either 101.325 kPa $\,\,_{306}$ ous studies reporting agreement of 4% on a different bench-

Temperature dependence. For a given compound, the 102) were rounded to exactly 1 atm (101.325 kPa). Tempera- 309 signs of the errors typically do not change at different temperatures (Fig. 1, Fig. 7). Furthermore, the magnitudes of The application of these filters (Table I) leaves 246 311 the error also remain largely constant (vertical lines in Fig. 1 conditions—where a condition here indicates a (molecule, 312 B), although several exceptions do occur. It is possible that temperature, pressure) tuple—for which both density and 313 these systematic density offsets indicate correctable biases

Outliers. The largest density errors occur for a num-290 tion II A for further description of the software pipeline used. 316 ber of oxygen-containing compounds: 1,4-dioxane; 2,5,8 $_{317}$ trioxanonane; 2-aminoethanol; dimethyl carbonate; for- $_{318}$ mamide; and water (Fig. 7). The absolute error on these $_{319}$ poor predictions is on the order of 0.05 g/ cm^3 , which is $_{320}$ substantially higher than the measurement error (≤ 0.008 $_{321}$ g/ cm^3 ; see Fig. 5).

We note that our benchmark includes a GAFF/AM1-BCC model for water due to our desire to automate benchmarks against a forcefield capable of modeling a large variety of small molecular liquids. Water—an incredibly important solvent in biomolecular systems—is generally treated with a special-purpose model (such as TIP3P [46] or TIP4P-Ew [11]) parameterized to fit a large quantity of thermophysical data. As expected, the GAFF/AM1-BCC model performs poorly in reproducing liquid densities for this very special solvent. We conclude that it remains highly advisable that the field continue to use specialized water models when possible.

2. Static dielectric constant

333

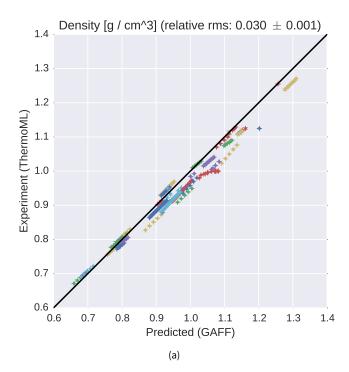

Overall accuracy. As a measure of the dielectric response, the static dielectric constant of neat liquids provides a critical benchmark of the accuracy electrostatic treatment in forcefield models. Discussing the accuracy in terms the ability of GAFF/AM1-BCC to reproduce the static dielectric constant ϵ is not necessarily meaningful because of the way that the solvent dielectric ϵ enters into the Coulomb potential between two point charges separated by a distance r,

$$U(r) = \frac{q_1 q_2}{\epsilon r} \propto \frac{1}{\epsilon}.$$
 (3)

 $_{342}$ It is evident that $1/\epsilon$ is a much more meaningful quantity $_{343}$ to compare than ϵ directly, as a 5% error in $1/\epsilon$ will cause $_{344}$ a 5% error in the Coulomb potential between two point $_{345}$ charges (assuming a uniform dielectric), while a 5% error $_{346}$ in ϵ will have a much more complex ϵ -dependent effect on the Coulomb potential. We therefore compare simulations against measurements in our ThermoML extract on the $1/\epsilon$ $_{349}$ scale in Fig. 2.

GAFF/AM1-BCC systematically underestimates the dielectric constants of nonpolar liquids. Overall, we find the dielectric constants to be qualitatively reasonable, but with clear deviations from experiment particularly for nonpolar liquids. This is not surprising given the complete neglect of electronic polarization which will be the dominant contribution for such liquids. In particular, GAFF/AM1-BCC systematically underestimates the dielectric constants for nonpolar liquids, with the predictions of $\epsilon \approx 1.0$ being substantially smaller than the measured $\epsilon \approx 2$. Because this deviation likely stems from the lack of an explicit treatment of electronic polarization, we used a simple empirical polarization model that computes the molecular electronic polarizability α as a sum of elemental atomic polarizability contributions [48].

From the computed molecular electronic polarizability α , an additive correction to the simulation-derived static dielectric constant accounting for the missing electronic po-

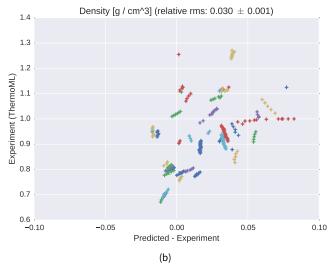

FIG. 1: Comparison of liquid densities between experiment and simulation. (a). Liquid density measurements extracted from ThermoML are compared against densities predicted using the GAFF / AM1-BCC small molecule fixed-charge forcefield. Color groupings represent identical chemical species, although the color map repeats itself due to the large (45) number of unique compounds. Plots of density versus temperature grouped by chemical species are available in Fig. 7. Simulation error bars represent one standard error of the mean, with the number of effective (uncorrelated) samples estimated using pymbar. Experimental error bars indicate the standard deviation between independently reported measurements, when available, or author-reported standard deviations in ThermoML entries; for some measurements, neither uncertainty estimate is available. See Fig. 5 for further discussion of error. (b). The same plot, but with the residual (predicted minus experiment) on the x axis. Note that the error bars are all smaller than the

symbols.

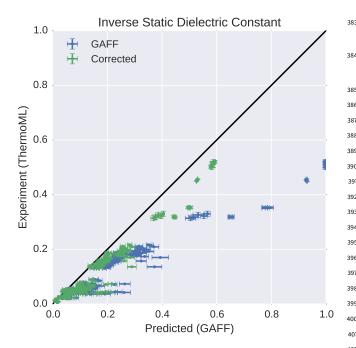

FIG. 2: Measured (ThermoML) versus predicted (GAFF / AM1-BCC) inverse static dielectrics (a). Simulation error bars represent one standard error of the mean.

Experimental error bars indicate the larger of standard deviation between independently reported measurements and the authors reported standard deviations; for some measurements, neither uncertainty estimate is available. See Fig. 5 for further discussion of error. See Section III B 2 for explanation of why inverse dielectric constant (rather than dielectric constant) is plotted. For nonpolar liquids, it is clear that the forcefield predicts electrostatic interactions that are substantially biased by missing polarizability. Plots of dielectric constant versus temperature grouped by chemical species are available in Fig. 8.

DISCUSSION

Mass densities

Our simulations have indicated the presence of systematic density biases with magnitudes larger than the measurement error. Correcting these errors may be a lowhanging fruit for future forcefield refinements. As an example of the feasibility of improved accuracy in densities, a recent three-point water model was able to recapitulate water density with errors of less than 0.005 g / cm^3 over temperature range [280 K, 320 K] [49]. This improved accuracy in density prediction was obtained alongside accurate predictions of other experimental observables, including static dielectric constant. We suspect that such accuracy might be obtainable for GAFF-like forcefields across some portion of chemical space. A key challenge for the field is to demarcate the fundamental limit of fixed-charge forcefields for predicting orthogonal classes of experimental observables. For example, is it possible to achieve a relative density error of 10^{-4} without sacrificing accuracy of other properties such as enthalpies? In our opinion, the best way to answer such questions is to systematically build forcefields with the goal of predicting various properties to within their known experimental uncertainties, similar to what has been done for wa-406 ter [11, 49].

Dielectric constants in forcefield parameterization

A key feature of the static dielectric constant for a liquid is that, for forcefield purposes, it consists of two very different components, distinguished by the dependence on the 411 fixed charges of the forcefield and dynamic motion of the 412 molecule. One component, the high-frequency dielectric 413 constant, arises from the almost-instantaneous electronic 414 polarization in response to the external electric field: this contributes a small component, generally around $\epsilon = 2$, which can be dominant for non-polar liquids but is completely neglected by the non-polarizable forcefields in common use for biomolecular simulations. The other compo-(4) 419 nent arises from the dynamical response of the molecule, through nuclear motion, to allow its various molecular multipoles to respond to the external electric field: for polar lig-A similar polarization correction was used in the develop- 422 uids such as water, this contributes the majority of the diment of the TIP4P-Ew water model, where it had a minor 423 electric constant. Thus for polar liquids, we expect the paeffect [11] because almost all the high static dielectric con- 424 rameterized atomic charges to play a major role in the static

Recent forcefield development has seen a resurgence nonpolar organic molecules; in the case of water, the em- 428 rameterization [13, 49]. However, a number of authors

Interestingly, recent work by Dill and coworkers [50] obity corrections to the static dielectric of 0.74 ± 0.08 . Taking 432 served that, for CCl_4 , reasonable choices of point charges the dataset as a whole, we find that the relative error in un- 433 are incapable of recapitulating the observed dielectric of corrected dielectric is on the order of -0.34 ± 0.02 , as comof $1.0 \le \epsilon \le 1.05$. This behavior is quite general: fixed

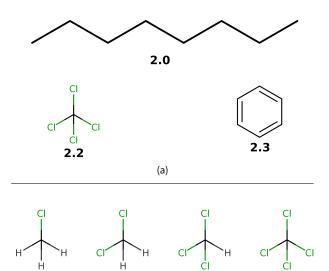

FIG. 3: Typical experimental static dielectric constants of some nonpolar compounds. (a). Measured static dielectric constants of various nonpolar or symmetric molecules [52, 53]. Fixed-charge forcefields give $\epsilon \approx 1$ for each species; for example, we calculated $\epsilon = 1.0030 \pm 0.0002$ for octane. (b). A congeneric series of chloro-substituted methanes have static dielectric constants between 2 and 13. Reported dielectric constants are at near-ambient temperatures.

12.9

₄₃₆ point charge forcefields will predict $\epsilon \approx 1$ for many nonpolar or symmetric molecules, but the measured dielectric constants are instead $\epsilon \approx 2$ (Fig. 3). While this behavior is well-known and results from missing physics of polarizability, we suspect it may have several profound consequences, which we discuss below.

Suppose, for example, that one attempts to fit force-443 field parameters to match the static dielectric constants of CCl₄, CHCl₃, CH₂Cl₂, and CH₃Cl. In moving from the it suddenly becomes possible to achieve the observed dielectric constant of 4.8 by an appropriate choice of point charges. However, the model for CHCl₃ uses fixed point charges to account for both the permanent dipole moment and the electronic polarizability, whereas the CCl₄ model contains no treatment of polarizability. We hypothesize that this inconsistency in parameterization may lead to strange 453 mismatches, where symmetric molecules (e.g. benzene and CCl₄) have qualitatively different properties than closely related asymmetric molecules (e.g. toluene and CHCl₃).

tant wherever we encounter the transfer of a polar molecule 508 (such as a peptide, native ligand, or a pharmaceutical small 509 surement and direct connection to long-range electrostatic molecule) from a polar environment (such as the cytosol, in- 510 interactions, static dielectric constants have high poten-460 terstitial fluid, or blood) into a non-polar environment (such 511 tial utility as primary data for forcefield parameterization

461 as a biological membrane or non-polar binding site of an enzyme or receptor). Thus we expect this to be implicated in biological processes ranging from ligand binding to absorption and distribution within the body. To understand this conceptually, consider the transfer of a polar smallmolecule transfer from the non-polar interior of a lipid bilayer to the aqueous and hence very polar cytosol. As a possible real-world example, we imagine that the missing atomic polarizability could be important in accurate transfer free energies involving low-dielectric solvents, such as the small-molecule transfer free energy from octanol or cyclohexane to water. The Onsager model for solvation of a dipole μ of radius a gives us a way to estimate the magnitude of error introduced by making an error of $\Delta \epsilon$ in the static dielectric constant of a solvent. The free energy of dipole solvation is given by this model as

$$\Delta G = -\frac{\mu^2}{a^3} \frac{\epsilon - 1}{2\epsilon + 1} \tag{5}$$

477 such that, for an error of $\Delta\epsilon$ departing from the true static dielectric constant ϵ , we find the error in solvation is

$$\Delta \Delta G = -\frac{\mu^2}{a^3} \left[\frac{(\epsilon + \Delta \epsilon) - 1}{2(\epsilon + \Delta \epsilon) + 1} - \frac{\epsilon - 1}{2\epsilon + 1} \right]$$
 (6)

For example, the solvation of water (a=1.93 Å, $\mu=2.2$ D) in a low dielectric medium such as tetrachloromethane or benzene ($\epsilon \sim 2.2$, but $\Delta \epsilon = -1.2$) gives an error of $\Delta \Delta G \sim$ -8 kJ/mol (-2 kcal/mol).

Implications for transfer free energies. As another ex-484 ample, consider the transfer of small druglike molecules 485 from a nonpolar solvent (such as cyclohexane) to water, a 486 property often measured to indicate the expected degree of lipophilicity of a compound. To estimate the magnitude of error expected, for each molecule in the latest (Feb. 20) FreeSolv database [15, 54], we estimated the expected error in computed transfer free energies should GAFF/AM1-BCC be used to model the nonpolar solvent cyclohexane 492 using the Onsager model (Eq. 6). We used took the cav- $_{
m 493}$ ity radius a to be the half the maximum interatomic dis- $_{\mbox{\tiny 494}}$ tance and calculated $\mu=\sum_i q_i r_i$ using the provided mol2 $_{\mbox{\tiny 495}}$ coordinates and AM1-BCC charges. This calculation pretetrahedrally-symmetric $\mathrm{CCl_4}$ to the asymmetric $\mathrm{CHCl_3}$, $_{_{496}}$ dicts a mean error of (-3.8 ± 0.3) kJ / mol [(-0.91 ± 0.07) 497 kcal / mol] for the 643 molecules (where the standard error 498 is computed from bootstrapping over FreeSolv compound measurements), suggesting that the missing atomic polar-500 izabilty unrepresentable by fixed point charge forcefields could contribute substantially to errors in predicted trans-502 fer and solvation properties of druglike molecules. In other words, the use of a fixed-charge physics may lead to errors ₅₀₄ of 3.8 kJ / mol in cyclohexane transfer free energies. We 505 conjecture that this missing physics will be important in the 506 upcoming (2015) SAMPL challenge [55], which will examine How important is this effect? We expect it to be impor- 507 transfer free energies in several low dielectric media.

Utility in parameterization. Given their ease of mea-

tency of fixed-charge models in low-dielectric media is suf- 566 membranes. ficiently alarming to motivate further study of polarizable forcefields. In particular, continuum methods [56-58], point dipole methods [59, 60], and Drude methods [61, 62] have 567 been maturing rapidly. Finding the optimal balance of accuracy and performance remains an open question; however, 568 methods [63] may provide polarizability physics at a cost not much greater than fixed charge forcefields.

C. ThermoML as a data source

523

The present work has focused on the neat liquid density and dielectric measurements present in the ThermoML Archive [18, 19, 64] as a target for molecular dynamics forcefield validation. While liquid mass densities and static dielectric constants have already been widely used in forcefield work, several aspects of ThermoML make it a unique resource for the forcefield community. First, the aggregation, 582 the Sloan Kettering Institute. support, and dissemination of ThermoML datasets through the ThermoML Archive is supported by NIST, whose mission makes these tasks a long-term priority. Second, the ThermoML Archive is actively growing, through partnerships with several journals, and new experimental measurements 584 properties contained in ThermoML—including activity co- 590 well. efficients, diffusion constants, boiling point temperatures, critical pressures and densities, coefficients of expansion, speed of sound measurements, viscosities, excess molar enthalpies, heat capacities, and volumes—for neat phases and mixtures represent a rich dataset of high utility for forcefield validation and parameterization.

CONCLUSIONS

High quality, machine-readable datasets of physicochemical measurements will be required for the construction of next-generation small molecule forcefields. Here we have discussed the NIST/TRC ThermoML archive as a growng source of physicochemical measurements that may be useful for the forcefield community. From the NIST/TRC ThermoML archive, we selected a dataset of 246 ambient, leat liquid systems for which both densities and static dielectric constants are available. Using this dataset, we benchmarked GAFF/AM1-BCC, one of the most popular small molecule forcefields. We find systematic biases in densities and particularly static dielectric constants. Element-based empirical polarizabilty models are able to account for much of the systematic differences between GAFF/AM1-BCC and experiment. Non-polarizable forcefields may show unac-

512 efforts. Although this will require the use of forcefields 564 ceptable biases when predicting transfer and binding propwith explicit treatment of atomic polarizability, the inconsis- 555 erties of non-polar environments such as binding cavities or

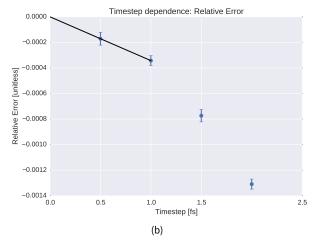

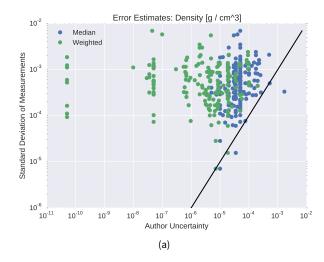

FIG. 4: Dependence of computed density on simulation timestep. To probe the systematic error from finite time-step integration, we examined the timestep dependence of butyl acrylate density. (a). The density is shown for several choices of timestep. (b). The relative error, as compared to the reference value, is shown for several choices of timestep. Error bars represent standard errors of the mean, with the number of effective samples estimated using pymbar's statistical inefficiency routine [39]. The reference value is estimated by linear extrapolation to 0 fs using the 0.5 fs and 1.0 fs data points; the linear extrapolation is shown as black lines. We find a 2 fs timestep leads to systematic biases in the density on the order of 0.13%, while 1 fs reduces the systematic bias to approximately 0.8%—we therefore selected a 1 fs timestep for the present work, where we aimed to achieve three digits of accuracy in density predictions.

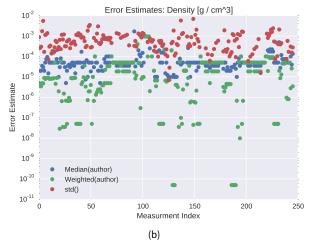

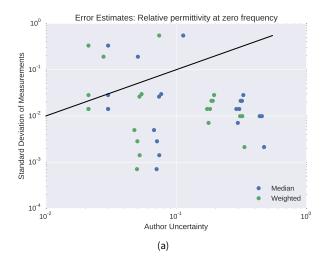

FIG. 5: Assessment of experimental error: Density To assess the experimental error in our ThermoML extract, we compared three different estimates of uncertainty. In the first approach (Weighted), we computed the standard deviation of the optimally weighted average of the measurements, using the uncertainties reported by authors ($\sigma_{Weighted} = [\sum_k \sigma_k^{-2}]^{-0.5}$). This uncertainty estimator places the highest weights on measurements with small uncertainties and is therefore easily dominated by small outliers and uncertainty under-reporting. In the second approach (Median), we estimated the median of the uncertainties reported by authors; this statistic should be robust to small and large outliers of author-reported uncertainties. In the third approach (Std), we calculated at the standard deviation of independent measurements reported in the ThermoML extract, completely avoiding the author-reported uncertainties. Plot (a) compares the three uncertainty estimates. We see that author-reported uncertainties appear to be substantially smaller than the scatter between the observed measurements. A simple psychological explanation might be that because density measurements are more routine, the authors simply report the repeatability stated by the manufacturer (e.g. 0.0001 g/ cm^3 for a Mettler Toledo DM40 [65]). However, this hardware limit is not achieved due to inconsistencies in sample preparation and experimental conditions; see Appendix in Ref. [20]. Panel (b) shows the same information as (a) but as a function of the measurement index, rather than as a scatter plot—because not all measurements have author-supplied uncertainties, panel (c) contains slightly more data points than (a, b).

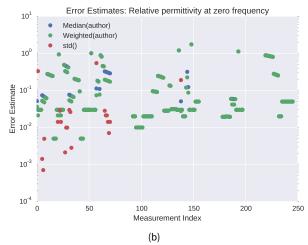

FIG. 6: Assessment of experimental error: Static **Dielectric Constant** To assess the experimental error in our ThermoML extract, we compared three different estimates of uncertainty. In the first approach (Weighted), we computed the standard deviation of the optimally weighted average of the measurements, using the uncertainties reported by authors $(\sigma_{Weighted} = [\sum_k \sigma_k^{-2}]^{-0.5})$. This uncertainty estimator places the highest weights on measurements with small uncertainties and is therefore easily dominated by small outliers and uncertainty under-reporting. In the second approach (Median), we estimated the median of the uncertainties reported by authors; this statistic should be robust to small and large outliers of author-reported uncertainties. In the third approach (Std), we calculated at the standard deviation of independent measurements reported in the ThermoML extract, completely avoiding the author-reported uncertainties. Plot (a) compares the three uncertainty estimates. Unlike the case of densities, author-reported uncertainties appear to be somewhat larger than the scatter between the observed measurements. Panel (b) shows the same information as (a) but as a function of the measurement index, rather than as a scatter plot—because not all measurements have author-supplied uncertainties, panel (c) contains slightly

more data points than (a, b).

1. Dependency Installation

```
The following shell commands can be used to install the
necessary prerequisites via the conda package manager for
Python:

conda config —add channels http://conda.binstar.org/omnia
cor $ conda install "openmoltools" "pymbar==2.1" "mdtraj==1.3" "openmm==6.3" packmol
Note that this command installs the exact versions used
in the present study, with the exception of openmoltools for
the present study, with the exception of openmoltools for
authors interested in extending the present work, we suggust using the most up-to-date versions available instead,
which involves replace the equality symbols == with >=.
